## BOARD OF DIRECTION

---

### *President*

W. P. WILTSEE, Chief Engineer, Norfolk & Western Railway, Roanoke, Va.

### *First Vice-President*

JOHN E. ARMSTRONG, Assistant Chief Engineer, Canadian Pacific Railway, Montreal, Canada.

### *Second Vice-President*

ROBERT H. FORD, Assistant Chief Engineer, Chicago, Rock Island & Pacific Railway, Chicago.

### *Past-Presidents*

W. D. FAUCETTE, D.Sc., Chief Engineer, Seaboard Air Line Railway, Norfolk, Va.

LOUIS YAGER, Assistant Chief Engineer, Northern Pacific Railway, St. Paul, Minn.

G. D. BROOKE, Vice-President, Chesapeake & Ohio Railway; New York, Chicago & St. Louis Railway, Cleveland, Ohio.

L. W. BALDWIN, Trustee, Missouri Pacific Lines, St. Louis, Mo.

JOHN V. NEUBERT, Chief Engineer Maintenance of Way, New York Central Railroad, New York City.

### *Treasurer*

A. F. BLAESS, Chief Engineer, Illinois Central System, Chicago.

### *Secretary*

E. H. FRITCH, 59 East Van Buren Street, Chicago.

### *Directors*

A. R. WILSON, Engineer Bridges & Buildings, Pennsylvania Railroad, Philadelphia, Pa.

T. T. IRVING, Chief Engineer (Central Region), Canadian National Railways, Toronto, Canada.

S. S. ROBERTS, Assistant Director, Bureau of Finance, Interstate Commerce Commission, Washington, D. C.

E. M. HASTINGS, Chief Engineer, Richmond, Fredericksburg & Potomac Railroad, Richmond, Va.

J. C. IRWIN, Valuation Engineer, Boston & Albany Railroad (N.Y.C.R.R.), Boston, Mass.

A. N. REECE, Chief Engineer, Kansas City Southern Railway, Kansas City, Mo.

DR. HERMANN VON SCHRENK, Consulting Timber Engineer, St. Louis, Mo.

GEO. S. FANNING, Chief Engineer, Erie Railroad, Cleveland, Ohio.

W. F. CUMMINGS, Assistant Chief Engineer, Boston & Maine Railroad, Boston, Mass.

# TABLE OF CONTENTS

## BUSINESS SESSION

|                                             | PAGE |
|---------------------------------------------|------|
| BUSINESS SESSION .....                      | 13   |
| Introductory Remarks by the President ..... | 13   |
| President's Address .....                   | 13   |
| Reports of Secretary and Treasurer .....    | 19   |
| Financial Statement .....                   | 32   |
| Condensed Report of Convention .....        | 45   |
| Report of Tellers .....                     | 48   |
| ADDRESS OF DEAN A. A. POTTER .....          | 53   |

## COMMITTEE REPORTS

|                                                                                                                                                                                                        |     |
|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|-----|
| REPORT OF SPECIAL COMMITTEE ON STRESSES IN RAILROAD TRACK .....                                                                                                                                        | 69  |
| Introduction .....                                                                                                                                                                                     | 69  |
| Laboratory Tests of Rail-Joints .....                                                                                                                                                                  | 72  |
| Tests of Rail-Joints on the Pennsylvania Railroad .....                                                                                                                                                | 130 |
| Tests of Rail-Joints on the Chesapeake & Ohio Railway .....                                                                                                                                            | 172 |
| Track Depression and Rail Stresses in Tests on the Chesapeake & Ohio Railway .....                                                                                                                     | 195 |
| Tests of GEO Track on the Missouri Pacific Railroad .....                                                                                                                                              | 224 |
| Discussion of Tests of Rail-Joints .....                                                                                                                                                               | 244 |
| Discussion of Tests of Track .....                                                                                                                                                                     | 278 |
| REPORT OF COMMITTEE ON UNIFORM GENERAL CONTRACT FORMS..                                                                                                                                                | 309 |
| Form of Agreement for the Purchase of Electrical Energy in Large Volume<br>(such as Required for Traction Purposes) .....                                                                              | 310 |
| Form of Conveyance of Title Granting the Right to Construct and Maintain<br>Buildings Over Railway Property .....                                                                                      | 320 |
| Form of Agreement for Pipe Line Crossings Under Railway Tracks .....                                                                                                                                   | 325 |
| Form of Agreement for Use of Railway Property by Pipe Lines Paralleling<br>Railway, with Special Reference to Pipe Lines Carrying High Pressure<br>Inflammable Oils and Gas .....                      | 325 |
| Form of Agreement with Public Authorities for Highway Grade Crossing<br>Elimination or Separation .....                                                                                                | 327 |
| REPORT OF COMMITTEE ON SIGNALS AND INTERLOCKING .....                                                                                                                                                  | 333 |
| Developments of Automatic Train Control .....                                                                                                                                                          | 333 |
| Increased Efficiency Secured in Operation by Signal Indication, Including<br>Remote Control of Switches, and Centralized Traffic Control, in Lieu<br>of Train Orders and Timetable Superiorities ..... | 335 |
| Synopsis of the Principal Current Activities of the Signal Section, ARA .....                                                                                                                          | 336 |
| REPORT OF COMMITTEE ON ELECTRICITY .....                                                                                                                                                               | 343 |
| Summary of Reports of Electrical Section, ARA .....                                                                                                                                                    | 343 |

|                                                                                                                                                                                                                                                     | PAGE |
|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|------|
| <b>REPORT OF COMMITTEE ON ROADWAY.....</b>                                                                                                                                                                                                          | 347  |
| Roadbed Drainage .....                                                                                                                                                                                                                              | 348  |
| Practice of Jacking Culvert Pipe Through Fills.....                                                                                                                                                                                                 | 355  |
| Bearing Power and Other Physical Properties of Soils, Including Effect Upon<br>Roadbed .....                                                                                                                                                        | 364  |
| Methods of Protecting Against Drifting Snow and Opening Snow Blockades....                                                                                                                                                                          | 370  |
| Methods of Protection Against Drifting Sand.....                                                                                                                                                                                                    | 376  |
| <b>REPORT OF COMMITTEE ON SHOPS AND LOCOMOTIVE TERMINALS....</b>                                                                                                                                                                                    | 403  |
| Turntables .....                                                                                                                                                                                                                                    | 403  |
| Power Plants .....                                                                                                                                                                                                                                  | 405  |
| Wheel-Removing Equipment for Engine Houses.....                                                                                                                                                                                                     | 409  |
| Car Paint Shops .....                                                                                                                                                                                                                               | 415  |
| <b>REPORT OF COMMITTEE ON YARDS AND TERMINALS.....</b>                                                                                                                                                                                              | 419  |
| Revision of Manual:                                                                                                                                                                                                                                 |      |
| Proposed Revision of Specified Items of Section of Manual Covering<br>Freight Yards .....                                                                                                                                                           | 420  |
| Proposed Revision of Rules for the Location, Maintenance, Operation and<br>Testing of Railway Track Scales.....                                                                                                                                     | 421  |
| Definition of a Standard Test of a Railway Track Scale.....                                                                                                                                                                                         | 433  |
| Grain Elevator Storage Yards and Plant Tracks.....                                                                                                                                                                                                  | 434  |

## BUSINESS SESSION

# PROCEEDINGS

---

The object of this Association is the advancement of knowledge pertaining to the scientific and economic location, construction and maintenance of Railways.  
Its action is not binding upon its members.

---

TUESDAY, MARCH 13, 1934

## MORNING SESSION

The Thirty-fifth Annual Convention of the American Railway Engineering Association was called to order in the Grand Ball Room of the Palmer House, Chicago, by the President, Mr. W. P. Wiltsee, Chief Engineer, Norfolk & Western Railway.

The President:—The meeting will please come to order. I will ask that the Board of Direction please come to the platform.

Thirty-five years ago a great and powerful organization was started, the main object of which was research as applied to the railroads. At that time there were very few such organizations, I am told not more than those you could count on the fingers of your hands, but now the number has increased to over 1500 in this country.

This meeting is also the annual session of the Construction and Maintenance Section of the American Railway Association, Division IV—Engineering, the meetings being concurrent.

The first order of business is the reading of the Minutes of the last annual meeting. Inasmuch as these Minutes have been printed and a copy furnished each member, the reading of the Minutes will be dispensed with, unless there is objection. I hear no objection; therefore the Minutes stand approved as printed.

## ADDRESS OF PRESIDENT W. P. WILTSEE

### General

At the time our Association was organized (more than thirty-five years ago), there existed very little uniformity in methods or devices used in construction and maintenance of way work, even under similar climatic and physical conditions.

The men who gathered together at the primary meeting on October 21, 1898, saw the necessity for an organization such as ours. One reason for its formation was to give an opportunity for discussion among its members and an interchange of views on matters which were of common interest. The field was broad and the subjects many, so since that time the work has been of great benefit, not only to ourselves but to our employers. These men probably had in mind that the first work to be done was to investigate and report on the fundamentals of railway engineering, but as the object of our Association, stated in the Constitution adopted at the Organization Meeting on March 30, 1899, is "the advancement of knowledge pertaining to the scientific and economic location, construction, operation and maintenance of railways", they had some vision of the present situation and the development of the art.

### Research

The fundamental work was completed many years ago and we have been engaged for years in research work of a high degree and the application of its results to our engineering problems. The term "Research", as I understand it, covers a wide and varied

field of endeavor in the search for knowledge. Between the acquirement of knowledge in the technical research work of the scientist and the observations made by the field engineer to substantiate this knowledge from performance there is a distinct connection; one is not complete without the other. The facts and laws discovered in the laboratory are of value only as they may be applied in the advancement of the art to the end that we may obtain more economic uses of materials and devices in the construction and maintenance of our railroads. Therefore, the laboratory research work, without the support of field observation, is of little profit.

To assist our Committees in experimental and laboratory research, arrangements have been made to establish a Director of Research and staff, functioning directly under a special Research Committee, to work with and direct experiments and other scientific research work that may be required by our Standing Committees.

A Committee on Railroads of the Science Advisory Board, composed of twelve outstanding men in industry, commerce and education, was formed at the suggestion of the Federal Coordinator to cooperate with a Committee of six Railway Executives in a survey of the research facilities and procedures now existing in the railroad and equipment organizations, and determine whether the principles of scientific research are being applied in the railroad industry as thoroughly and effectively as practicable.

## **Publications**

Publications have been issued as in the past. No new Manual has been printed, but the additions to the Manual were published in Bulletin form, as customary. The value of our work, as recorded in our Manual of Recommended Practices, is shown by the action of the railroads in putting these practices more and more into use. During the past year a plan has been put into effect, with a view to increasing the use of our Recommended Practices, by which questionnaires on several recommendations of the Association have been sent to the Railway Executives to determine whether they are now using or will use them as standard.

## **Finances**

It is very gratifying to state that the Association is in sound financial condition. The operations during the calendar year show a substantial excess of receipts over disbursements. (The excess of receipts over disbursements was \$3,964.99.)

## **Membership**

It is to be deeply regretted that it is necessary to report a decrease in the number of members on the rolls. This situation is due to the economic conditions prevailing for the past four years. Reductions in forces, consolidation of positions, and so forth, have made it imperative, in many cases, for members affected to withdraw their affiliation in order to conserve their resources. It is hoped that with improvement in business the ground lost in this respect will be more than recovered, and that many former members will renew their membership.

In the current Bulletin the members will find a blank application for membership. It is urged that members detach this form and hand it to some eligible prospective member.

## **Deceased Members**

During the year the Association has sustained the loss by death of a number of valued members, among them being Charles S. Churchill, Charter Member and Past-

President; M. L. Byers, Charter Member; Sir Henry W. Thornton; B. E. Holloway; G. E. Tebbetts; W. A. Christian and J. H. Gibboney, who was Chairman of our Arrangements Committee this year.

### Committee Reports

The reports prepared by the several committees to be submitted for action at this Annual Meeting, compare favorably, both in quality and volume, with those offered in any preceding year. Committees have labored earnestly and painstakingly to prepare reports of outstanding value. Chairmen and members of Committees are to be complimented on their good work, and they have our grateful appreciation.

The thirty Standing and Special Committees are constantly engaged in research, not only that obtained through experiments of their own and other scientific bodies, but in service tests and summarizing the accumulated experience and records of all the railroads of the country.

The work originally contemplated by the Committee on Stresses in Railroad Track is now coming to a close, and this Committee has produced information that will be very valuable in its application to the design of our track structures. This Committee should be continued and the work extended.

During the past year the Committee on Rail Investigations has presented information that is worth a great deal to the railroads, in that their experiments have shown at least one cause to which transverse fissures in rails can be traced, and how they develop in track under heavy wheel loads.

### Amendment to Constitution

At the request of the required number of members, an amendment to the Constitution was submitted to letter-ballot of the membership and adopted. The amendment related to the manner of placing the names of candidates for offices on the ballot. The Constitution now requires that where there is more than one candidate for any office, the names of candidates shall be placed in alphabetical order on the ballot. The proposed amendment provides that the order in which names are to be placed on the ballot shall be determined by lot by the Nominating Committee.

### Honorary Membership

During the past year, the Board of Direction has conferred Honorary Membership on two highly respected and valued members: Past-President George Watson Kittredge and Doctor Arthur Newell Talbot, in recognition of distinguished services rendered the Association. Mr. Kittredge was the second President, and successfully piloted the Association during its formative period. Dr. Talbot's outstanding work as Chairman of the Committee on Stresses in Railroad Track and his valuable contributions to other activities of the Association amply warrant this honor.

### Cooperative Activities

Contact has been maintained with other organizations on matters of mutual interest. Among such organizations are the following:

- American Standards Association
- American Society for Testing Materials
- Portland Cement Association
- University of Illinois
- National Crushed Stone Association
- Manganese Track Society

National Scale Men's Association  
National Board of Fire Underwriters  
Railway Fire Protection Association  
American Transit Association  
American Society of Municipal Engineers  
American Petroleum Institute  
Chemical Welfare Service, U.S. Army,

in addition to the several Divisions and Sections of the American Railway Association.

### **Special Committee on "Complete Roadway and Track Structure"**

A new Special Committee has been authorized by the Board of Direction, entitled, "Complete Roadway and Track Structure", with instructions to study and report on "Complete roadway and track for various loads and traffic densities".

### **Revision of Portfolio of Trackwork Plans**

Numerous changes and additions to the trackwork plans in recent years have made it necessary to reprint the portfolio and bring the volume up to date. The Track Committee has accordingly given this matter intensive study during the year and will submit a complete revision for approval at this Convention. The revised portfolio will be made available to the members as soon as practicable after the Annual Meeting.

### **Scales Used in Railway Service**

It may be of interest to note that the "Specifications for the Manufacture and Installation of Motor Truck, Built-in, Self-Contained and Portable Scales for Railway Service", formulated by the Committee on Yards and Terminals, and shown on pages 447 to 462, inclusive, of Bulletin 361, have been printed as formal specifications for the City of New York. The reference is "New York City Specification 40-S-52".

### **Cooperation With Section of Purchases**

The staff of the Federal Coordinator, through its Section of Purchases, has indicated its intention to make use of existing specifications for materials used by railways where such exist, rather than create standards of its own. Therefore, the American Railway Engineering Association has been urged to review such specifications with a view to making them available as standards for railway use. The Committees concerned are now giving these requests prompt attention. A survey has been made at the request of that Staff to ascertain the extent of use of the American Railway Engineering Association specifications, especially those involving materials. The results of this survey have been reported to the Director of Purchases.

### **Statement by the Federal Coordinator**

Mr. Joseph B. Eastman, Federal Coordinator of Transportation, on October 6, 1933, transmitted a statement to the several Regional Coordinating Committees, with respect to the standardization of lumber, rail sections, rail joints and other accessories, in addition to a number of subjects pertaining particularly to the Mechanical Division and other Divisions of the American Railway Association.

The respective Committees of the American Railway Engineering Association were instructed to give preferred attention to these several matters. The present status of the items quoted above is as follows:

## Standardization of Lumber

The Recommended Practices for Lumber and Timber now in the Manual, have been reviewed carefully by a Special Committee, composed of those experienced in the manufacture and purchase of lumber. The result of their study is to the effect that they are in conformity with the American Lumber Standards, although more work should be done to make them more readily usable by the purchaser; and that there is no lack of harmony between the Recommended Practices of the Engineering Division and the Mechanical Division of the American Railway Association.

## Rail Sections

At the 1933 Convention, a section weighing 131 pounds per yard was adopted, superseding the 120, 130 and 140-pound RE Rail Sections. In July, 1933, a section weighing 112 pounds per yard was submitted to letter-ballot and adopted; this section to supersede the present 110-pound RE Rail Section. The 90 and 101-pound Rail Sections, now in the Manual, will not be changed.

## Rail Joints and Other Accessories

A Joint Bar and Assembly for 112-pound rail was submitted to letter-ballot on January 20, 1934 and adopted. A Joint Bar and Assembly for 131-pound rail will be submitted to this Convention for adoption. Plans of Tie Plates have been submitted by the Track Committee, and are also offered for adoption at this Convention.

## Recommendations

This is the thirty-fifth annual assembly of your Association. You may well feel a pardonable pride and satisfaction in its records of fulfillment from year to year, which achievement warrants the hope and expectation that the progress in future will measure fully up to the high standards of the past. In order to assist in accomplishing this, I have a few recommendations to offer:

1. Careful examination of the Manual and immediate steps to be taken to bring the subject-matter up to date.
2. That our Committee eliminate men who are not taking an active interest in the work, and thus tend to produce more active standing committees.
3. Amend our General Rules for the Preparation, Publication and Consideration of Committee Reports to require approval by letter-ballot on items that are adopted as Recommended Practice by the Convention, before printing in the Manual. This will give added importance to these items, and tend, not only to increase the standard of our work, but to extend their use as standard by the carriers.
4. That the Chairman of each Committee cooperate more fully with the other Divisions of the American Railway Association on any subject under consideration in which these other Divisions have an interest.

IN CONCLUSION, I wish to thank all those who have been associated with me during my term in this office, and those who have so successfully carried on its committee-work; the members of the Board of Direction who have assisted me very much in many ways by their advice and recommendations, and especially in granting me unusual authority in handling matters that have arisen from time to time during the past year that were different from any of our past experiences and which required prompt decisions; the Chairmen and members of the Committees who have devoted their time to making this year a success; and, particularly, to the Committee on Outline of Work, which has had

a very difficult task during the past year in assigning the subjects in such a way as to avoid unnecessary time being spent on subjects of little, if any, value, and in avoiding duplication of work.

Our able Secretary who has completed thirty-five years of loyal and efficient service, I thank for the way he has handled the duties of his office, thus contributing very much to the pleasure of your President in serving you this past year (Applause).

The next order of business is the report of the Secretary and Treasurer.

(Secretary Fritch abstracted the reports of the Secretary and of the Treasurer.)

# REPORT OF THE SECRETARY

March 1, 1934.

## To the Members:

The thirty-fifth annual report on the general affairs of the American Railway Engineering Association is respectfully submitted herewith.

The past twelve months have been an unusually active period, especially in committee-work, which is the foundation of the organization's activities. From even a cursory or superficial inspection of the twenty-eight reports which are presented for approval and action at this convention, it will be apparent that a prodigious amount of work has been accomplished during the year.

Following the enactment of the Transportation Act of 1933, and the setting up of the staff of the Federal Coordinator of Transportation, instructions were received to cooperate with these Government agencies to the fullest extent. Your Association, through its committees, has whole-heartedly carried out those instructions. Contact was at once established with the Section of Purchases of the Coordinator's staff. It was gratifying to be assured from those in responsible charge of the Government's organization that they proposed to recognize the AREA recommended practices wherever applicable rather than set up standards of their own, and that they intended to promote and extend the use of such recommended practices wherever practicable.

The primary concern of the Government body was to promote those standards involving the greatest expenditure, for the ultimate purpose of increasing employment. A survey of the entire field was made and the most conspicuous examples selected for standardization. These included, first, rail and the necessary fastenings. It was intimated that rail sections should preferably be reduced in number to not more than five, preferably four. The Association, at its last annual meeting, had already adopted a rail section weighing 131-lb., this section to supersede the former 120-lb., 130-lb., and 140-lb. RE sections. The Committee on Rail was accordingly instructed to give this item preferred attention. A section weighing 112-lb. per yard was designed, and on account of the urgency of the matter, the new design was submitted to letter-ballot on July 1, 1933, and approved by a large majority of the members voting.

The Association had not heretofore designed joint-bars, and in line with instructions, gave intensive study to preparing plans for these devices for the several rail sections. A joint-bar and assembly for the 112-lb. rail section was formulated and submitted to letter-ballot on January 20, 1934. This was also adopted by a majority of the members voting. A joint-bar for the 131-lb. RE section will be submitted in a supplemental report by the Committee on Rail.

The subject of standard plans for tie plates was assigned to the Committee on Track on September 21, 1933. Work on this assignment was undertaken immediately, and as a result of its studies, the Committee formulated plans for 10-in., 11-in., 12-in. and 14-in. tie plates, which are being submitted for approval at this convention.

Plans and specifications for various track tools have been prepared during the year and are offered for approval as recommended practice.

Other items of trackwork and specifications therefor are under active consideration and will be reported out as rapidly as conditions warrant.

One of the features that is of interest is the requirement of the Coordinator's staff that manufacturers of devices used in the railway field be consulted in the preparation of standards. Committees of the AREA have invited the cooperation of manufacturers on subjects in which they are concerned, in order that a standard when promulgated is practicable and can be made economically.

The following list of organizations with which committees have cooperated will indicate the wide range of activities involved in such collaboration:

- American Railway Association, Mechanical Division
- American Railway Association, Purchases and Stores Division
- American Petroleum Institute
- American Society of Civil Engineers
- American Society for Testing Materials
- American Society of Mechanical Engineers
- American Standards Association
- American Transit Association
- American Wood Preservers' Association
- Central Committee on Lumber Standards
- Chemical Warfare Service, U.S. Army
- Forest Products Laboratory
- Edison Electric Institute
- Forged Tool Society
- Joint Committee on Automatic Train Control
- Joint Committee on Concrete and Reinforced Concrete
- Joint Committee on Grade Crossing Protection
- Joint Committee on Railway Sanitation
- Manganese Track Society
- National Bureau of Engineering Registration
- National Scalemen's Association
- Portland Cement Association
- Rail Manufacturers' Technical Committee
- Railway Fire Protection Association
- University of Illinois, Engineering Experiment Station

**Trackwork Plans.**—For a number of years, the Committee on Track has actively cooperated with the Manganese Track Society, composed of the principal firms manufacturing frogs, switches, crossings, etc., in the preparation of plans for such track devices. To date, 187 plans, and specifications therefor, have been prepared and adopted. In view of developments, it has been found necessary to make a complete revision of these plans. The portfolio has been entirely reprinted, and copies will be available immediately after the convention. This is one of the outstanding achievements of the Association, and is in the direction of simplification and standardization. The preparation and printing of this Portfolio of Trackwork Plans involved an expenditure of upwards of twenty-five thousand dollars.

**Research.**—The Federal Coordinator of Transportation, in an address delivered at Chicago last November, referred to the research work carried on by large industries, and the benefits derived therefrom, and suggested that possibly similar results could be accomplished by railroads, with consequent benefit to the transportation industry. Possibly as a sequel to that suggestion, a Science Advisory Board, composed of leading scientists engaged in research

work for large industries, and educators, was appointed by President Roosevelt, to which were added six Railway Executives, for the purpose of ascertaining what railroads had done in the past or were doing currently, in the way of research or investigational work.

A survey has been made of the Association's activities along the line of this inquiry, and the results have been transmitted to the President of the American Railway Association, for presentation to the Science Advisory Board for its comments and recommendations.

Upon authorization of the Board of Directors of the American Railway Association, the Mechanical Division has set up a Research Bureau, with a Director in charge. The Freight Claim Division has also organized a staff, and is proceeding along somewhat similar lines.

At a meeting of the Board of Direction of your Association and of the General Committee of the Engineering Division, held on January 30, 1934, the question of establishing a similar Research Bureau for the Engineering Division was submitted for determination. As a result of the deliberations, it was voted to recommend to the American Railway Association the establishment of a Research organization, with a Director, Assistant Director, and the necessary clerical staff, which recommendation has been transmitted to the President of the ARA for action and authorization by its Board of Directors.

**Honorary Membership.**—During the year, Honorary Membership was conferred by the Board of Direction on George Watson Kittredge, second President of the Association, and on Dr. Arthur Newell Talbot, Chairman of the Special Committee on Stresses in Railroad Track, for outstanding contributions to the Science of Railway Engineering.

**Changes in Titles of Committees.**—The Board of Direction has approved changes in the titles of three Committees: Committee IX—Grade Crossings, has been changed to "Highways"; Committee XXV—Rivers and Harbors, to "Waterways and Harbors;" and Committee XIII—Water Service and Sanitation, to "Water Service, Fire Protection and Sanitation," these changes being considered as more in line with the functions of the respective committees.

**Formation of a New Special Committee.**—To dispense with a large amount of collaboration, the Board of Direction has authorized the formation of a new special committee, entitled "Special Committee on Roadway and Track Structure," its assignment reading, "Complete roadway and track for various loads and traffic densities."

**Vacancy in Board of Direction.**—By reason of leaving railway service, Lem Adams, who was elected a Director at the last annual meeting, resigned, and the Board appointed Dr. Hermann von Schrenk to fill the vacancy.

**A Deserved Recognition.**—J. C. Irwin, Representative of the American Railway Association—Engineering Division, on American Standards Association, has been elected Chairman of Standards Council of that important organization.

**Translation of Table of Contents of Manual.**—Emilio Lenhardtson, a valued member of the Association, with headquarters at Buenos Aires, Argentine, South America, has translated the table of contents of the 1929 Manual into the Spanish language for the information of Engineers in that country. This translation involved a large amount of painstaking labor.

**Amendment to Constitution.**—An amendment, proposed by the requisite number of members, relating to the manner of placing the names of candidates for offices on the ballot, when there is more than one candidate for any office, was submitted to the membership by letter-ballot. The result of the vote is:

|                                    |           |
|------------------------------------|-----------|
| For the amendment.....             | 636 votes |
| Against the amendment.....         | 91 votes  |
| Defective votes (not counted)..... | 39 votes  |

The amendment having been approved, it will become effective subsequent to the adjournment of the annual meeting.

**Membership.**—The membership rolls show a decrease from the number reported on a year ago. The appended table sets forth the present status of the membership:

|                                              |      |       |
|----------------------------------------------|------|-------|
| Membership on rolls as of March 1, 1933..... | 2311 |       |
| Additions during the year.....               | 20   |       |
| Reinstatements .....                         | 24   |       |
|                                              |      | <hr/> |
|                                              |      | 2355  |
| Losses by death .....                        | 21   |       |
| Resignations .....                           | 65   |       |
| Dropped .....                                | 241  | 327   |
|                                              |      | <hr/> |
| Membership as of March 1, 1934.....          |      | 2028  |

The past four years have been exceedingly difficult for many of our members, and who have been adversely affected by the economic conditions. The Board of Direction has dealt with this situation in a sympathetic manner, which has been duly appreciated by those concerned. It is gratifying to report that improved conditions indicate the resumption of their membership affiliation of a substantial number of former members.

In the back of the current numbers of the Bulletin, a blank form of application is included. The individual members are requested to detach this form and hand it to an eligible prospect and urge that it be filled out and sent to the Secretary's office.

**Deceased Members.**—It is with deep regret that we record the loss of twenty-one valued and loyal members during the year. The names of our departed associates are given in a following page.

**Finances.**—The Financial Statement, shown in Exhibit 1, indicates that the Association's financial condition is very satisfactory, considering the business conditions prevailing for the past four years.

The losses in number of members has naturally affected our revenues, but with better or improved business, the lost ground will be recovered.

**Acknowledgment.**—The loyal, faithful and efficient services rendered by the staff is hereby gratefully acknowledged.

*E. V. Fritch*

Secretary.

## Exhibit 2

## SYNOPSIS OF COMMITTEE REPORTS

**Roadway** (GEO. S. FANNING, *Chairman*).—The current report is the conclusion of the subject of "Methods of Roadbed Drainage," in accordance with the plan adopted in 1931. The present report covers (c) Maintenance of ditches and drains; special problems of maintenance—soft spots and water pockets; and slides. Changes in the Manual are recommended in order to bring the definitions and the Specifications for the Formation of the Roadway in harmony with the recommended practice adopted for roadway drainage, to withdraw from the Manual present matter on slides, water pockets, soft spots and ditching, the substance of which is included in the current report or is obsolete, and to replace the illustrations in the Manual relating to drainage with more comprehensive plates. . . . The practice of various railroads as to jacking culvert pipe through fills is reported on and illustrated. The conclusions of the Committee are that where conditions are suitable, the placing of pipe culverts by the jacking process is feasible and will save from 30 to 50 per cent of the cost of placing the pipe by the open trench method and will be cheaper than tunneling. The advantages of the method, cited by the Committee are—usually lower cost; no interruption to traffic, minimum disturbance of roadbed, and consequently little or no subsequent settlement. . . . The subject, bearing power of soils, has been enlarged upon this last year by the assignment of the broader field of the bearing power and other physical properties of soils in addition to consideration of their effect on roadbed performance. A terminology of soils is presented as a preliminary listing of soil characteristics. The current report deals with terms identifying soils, texture, structure, consistence, compactness and cementation. . . . A year ago, methods of protecting against drifting snow and of snow removal on the line and in yards and terminals was reported on. In the current report the assignment was modified and treated under the title, methods of protecting against drifting snow and opening snow blockades. The report has been subdivided into protection against drifting snow and opening snow blockades, and providing for revision of certain material in the Manual. . . . A new subject, methods of protection against drifting sand, has been extensively reported on in the current report. The Committee has accumulated a large amount of interesting information in regard to methods for protecting against this menace from various parts of the world.

**Ballast** (A. P. CROSLY, *Chairman*).—Samples of gravel ballast have been collected through cooperation of railroads and gravel producers, and subjected to abrasion, crushing, specific gravity, absorption, grading, weight, void, and soundness tests. Information concerning the service record in the track of most of these samples has been furnished the Committee by railroads. It is proposed to continue these tests and report thereon in future. . . . Further study has been given to the specifications for stone ballast, including best method of testing resistance to weathering; study has also been given to the subject of cementing value. The Committee contemplates initiating a co-operative series of cementing value tests, with the hope of obtaining information of practical value for use in specifications for ballast. . . . The Committee has endeavored to secure data on comparative cost of maintaining track on various kinds of ballast, but little information has been obtained. . . . As a result of its study on the subject, proper depth and kind of sub-ballast, the Committee recommends a revision of the conclusions in the Manual under the heading, proper depth of ballast. In considering the subject, a distinction has been made between new construction and old established lines.

**Ties** (W. J. BURTON, *Chairman*).—The Committee proposes a revision of the Specifications for Cross- and Switch-Ties, relating to split and dimensions, and presents arguments in support thereof. . . . The benefits to railroads of strictly adhering to the standard tie specifications are pointed out. . . . The customary annual report on installations of substitute ties is presented, together with a summary of tests of substitute ties now in progress.

. . . The tie renewal statistics for railroads of the United States were issued in the June Bulletin (see page 71, No. 356). The corresponding data for the three principal Canadian railways is included in the current report. . . . A comprehensive report is presented on standard spacing of spike holes for ties preadzed and bored for standard rail sections of 90-lb. to 131-lb. inclusive. A number of recommendations are made and request that the subject be reassigned for further study. . . . A particularly interesting and valuable report is that relating to a method of predicting tie renewals, including a change from untreated to treated ties. The report covers definitions of terms; general discussion of renewal predictions; procedure for making predictions; method of determining approximate average life of ties in track. . . . The type of tie plate best adapted for use with pre-adzed ties is discussed. The Committee recommends a plate of adequate size and proper design to afford maximum protection from mechanical wear. If plates with ribs are used, the Committee recommends the grooving for these ribs in connection with pre-adzing. . . . A study has been made of the economy of use of tie plates which are secured to the tie independently of the rail fastenings, with particular reference to the effect on tie life. The replies to a questionnaire on the subject are commented on. . . . The Committee presents a comprehensive report on methods of inspection for renewal of ties, checking thereof and adherence thereto. The replies to a questionnaire are analyzed and commented on. As a result of its study, the Committee offers a series of conclusions, which in its judgment, under most conditions, will bring about safe and economical control of tie renewals.

**Rail (EARL STIMSON, *Chairman*).**—The Committee proposes a number of changes in the chapter on "Rail" in the Manual. . . . Progress is reported on the joint investigation being conducted at the University of Illinois on the cause and remedy for transverse fissures and other rail failures. This investigation is now in its third year and definite progress is being made. . . . One of the features of the annual report is the compilation of rail failure statistics. The current report contains the statistics for the year 1932. Similar statistics are presented on transverse fissure failures. . . . The operations of the ARA Detector Car are reported on, indicating that a total of 6600 track miles were tested during the year. . . . The Committee has given further study to the cause and prevention of rail battering. Various methods of heat treating rail ends are described, and the Committee recommends that the heat treating of rail ends be generally followed in the case of new rail, cropped rail, or where rail batter has not progressed to an objectionable extent. . . . As a result of its study of the question of rail lengths in excess of 39 ft. (the present standard), the Committee reports that it feels the majority of roads are not prepared at this time to agree on a standard length in excess of 39 ft. . . . The results of tests of alloy and heat treated carbon steel rails are presented. . . . During the year, the Committee gave intensive study to redesigning rail sections heavier than 100-lb. per yard, so as to obtain the most economical distribution of metal with the maximum strength of section. A section weighing 112.4-lb. per yard was developed. Action on the Committee's recommendation could not be deferred until the annual meeting, the section was therefore submitted to the membership by letter-ballot, dated July 1, 1933. The recommendation was approved by a large majority vote. The new section supersedes the former 110-lb. RE section. . . . The subject of design of joint bars for RE rail sections was assigned to the Committee during the year, with instructions for early report. This topic was also given immediate and preferred attention, and a joint bar section and assembly for use with the 112-lb. RE section was developed. As there was need for early action, the Committee's recommendation was submitted to letter-ballot, dated January 20, 1934. A joint-bar section and assembly for use with the 131-lb. RE section has been issued as a Supplemental Report.

**Track (C. J. GEYER, *Chairman*).**—Intensive study has been given to revision of the chapter on "Track" in the Manual, and a number of important changes are recommended. An addition to the specifications for soft steel cut track spikes is submitted. As information and for criticism, plans are presented for 9/16-inch and 5/8-inch raised throat cut track spikes. . . . Dur-

ing the year, study has been given to plans and specifications for track tools, resulting in a series of plans and specifications, which are offered for approval. The Committee proposes making further study for additional tools adapted to use in modern track maintenance and construction, particularly as regards tools used in laying and handling heavy rail. . . . Specifications for adjustable guard rail clamps are offered for approval. . . . With the view of securing information relative to possible limits in the use of roller bearings on curves, a circular of inquiry was sent to large manufacturers of roller bearings, and the data obtained is submitted as information. . . . On September 21, 1933, the subject of design of tie plates for RE rail sections was assigned to the Track Committee. As result of a thorough study given these instructions, the Committee has prepared a series of plans for tie plates, which are offered for approval as recommended practice. On account of the urgent need for tie plate standards and due particularly to the adoption of the new rail sections, the plans are submitted for approval as recommended practice at this time rather than as information. . . . Progress is reported on the practicability of using reflex units for switch lamps and targets. . . . The replies received in answer to a questionnaire on desirable tightness of track joints and effect upon life of rail and joints, and of loose joints, have been summarized and from these replies a series of conclusions have been derived. . . . An interesting report is that on methods of reconditioning of rail ends, fastenings, frogs and switches in track. A comprehensive tabulation of replies to a questionnaire is included. . . . A final report is made on damage to track and devices due to brine drippings from refrigerator cars, including the conclusions and recommendations of a joint sub-committee.

**Buildings** (G. A. RODMAN, *Chairman*).—Revised Specifications for Built-up Roofing are submitted to supersede similar specifications in the Manual. . . . Continuing its assignment, preparation of Specifications for Railway Buildings, sections on steel chimneys—welded; genuine wrought iron chimneys; built-up roofing; wood screens, and metal screens, are presented for information and criticisms. The preparation of these various sections, now numbering over thirty, has extended over a series of years, and is of great practical value to the Railway Engineer. . . . An interesting report is that on the subject of the relative merits of wood and fireproof roof structures, including wood, hollow tile fireproofing, concrete, cement tile, etc. The report includes a table on the relative merits of different types of wood structures. . . . The Committee has given active study to the causes of dust explosions in grain elevators and to methods of obviating the hazard. The Department of Agriculture reports that during the last fourteen years dust explosions in the United States in plants handling grain and grain products caused the loss of 277 lives, injury to 487 employees, and property damage amounting to more than thirty million dollars. The Committee has assembled a large amount of data and presents it in interesting form. A series of conclusions are offered, outlining methods by means of which dust explosions can be reduced.

**Wooden Bridges and Trestles** (H. AUSTILL, *Chairman*).—A number of minor revisions of the chapter on Wooden Bridges and Trestles as now appearing in the Manual are submitted. . . . Under the assignment, overhead wooden or combination wooden and steel highway bridges, study has been given to the specifications for timber piles included in the Manual, and it is considered that the dimensions of piles as specified are larger than required for use in highway bridges. A table of dimensions for first-class piles for highway bridges is presented. . . . On the subject, design of standard wooden trestles for heavy loading, the Committee states that the present plans in the Manual provide for a live load of Cooper's E-45 and E-60, and that its study of modern locomotives indicates loading considerably in excess of these design loads. A table is presented giving the axle loading and Cooper's rating for 14-ft. span for a few typical modern locomotives; another table gives a comparison of unit stresses for a selected number and size of stringers for open and ballasted deck. A statement is presented prepared by J. A. Newlin, a member of the Committee, giving the results of an extensive series of tests to determine horizontal shear stresses and their distribution in the beam. . . .

A valuable report is submitted by the Committee on methods of strengthening existing bridges. . . . During the year the Committee has given study to the design of washers, separators, cap stringer straps, and other trestle fastenings, and considered the practice of a number of roads. The Committee contemplates preparing designs of washers, separators, and fastenings and present them in a future report.

**Masonry** (M. HIRSCHTHAL, *Chairman*).—Progress is reported on the subject of reinforced concrete arches, and the Committee indicates it proposes to review the material now presented and that included in previous reports, and to submit to the next annual meeting for approval as recommended practice specifications for the design and construction of reinforced concrete arches for railroad loadings. . . . Drawings of reinforced concrete trestles design for E-60 loading are submitted for approval as recommended practice. . . . The Committee continues to report on progress in the science and art of concrete manufacture, presents a valuable contribution on vibration in placement of concrete, including a selected bibliography on high-frequency vibration of concrete. Other phases of this same general subject are treated under the sub-headings, central mixed and transit mixed concrete, and segregation. . . . On the subject of foundations, definitions for "Foundations" and for "Substructure" are offered for approval. A general specification for foundations for railway structures is submitted for information and criticism. . . . Tentative specifications for lining railway tunnels with concrete are offered for information and comments. . . . An interesting report is that on pneumatically projected concrete, including tentative specifications for "shotcrete". . . . The Committee has continued its study of design of expansion joints involving masonry structures, and has collected a number of plans covering various types of joints involving masonry structures under varying conditions. These sketches are illustrated, together with comments thereon.

**Grade Crossings** (J. G. BRENNAN, *Chairman*).—Active study over a period of two years has been given to the preparation of specifications for street crossings over railway tracks, both steam and electric. Four specifications are submitted, the first three for approval, the fourth as information, namely: Specifications for preparation of track structure, width of crossing and approaches for construction of street crossings over railway tracks; specifications for the construction of rail type street crossings; specifications for the construction of wood plank street crossings; and specifications for the construction of highway crossings surfaced with oil processed gravel. . . . An interesting report is submitted on the relative economy of different types of grade crossings. The report is grouped under plank, bituminous, concrete, metal and paved crossings. A statement is included giving some of the advantages and disadvantages of the various types of crossings. . . . A valuable report is that on the proper vertical curves on highways for grade separation projects, together with a recommendation that depression or elevation of highways required for separation from railroad grades be effected with the minimum of vertical curvature required for safety and utility. . . . The Committee has investigated the merits and economy of the "stop-and-go" type of signal with red and green illuminated aspects, as a protective device at highway-railroad grade crossings, under usual conditions and under special conditions, and concludes that such signals should not be used for the protection of railroad-highway grade crossings where they are operated exclusively by the passage of trains, but that their use should be confined to special locations where their observance can be enforced by police power.

**Signals and Interlocking** (P. M. GAULT, *Chairman*).—The province of this Committee is to keep the members of the AREA informed of developments in signaling and interlocking. In the current report, the developments in automatic train control are recorded. In previous years the Committee has presented reports showing the savings and increased efficiency secured in railway operation by signal indications in lieu of train orders and timetable superiorities. The present report relates to intangible benefits and savings difficult to determine accurately provided by centralized traffic control installation.

. . . The report gives a synopsis of the principal current activities of the Signal Section, supplemented with list and references by number of adopted specifications, designs, and principles of signaling practice.

**Records and Accounts** (C. C. HAIRE, *Chairman*).—One of the noteworthy accomplishments of this group during the year is the revision of the conventional signs for use on railway profiles, right-of-way and track maps. The preparation of this document has involved a very large amount of painstaking labor on the part of this Committee. . . . Another valuable contribution is the report on joint facility records. Suitable forms for handling joint facility records are submitted, with the view of making the billing between roads less troublesome, and of simplifying the rendering and checking of joint facility bills. . . . Revised forms for bridge inspection report, wood boxes and pipe culvert inspection report, and bridge, trestle and culvert inspection report forms are submitted to supersede corresponding forms now in the Manual. . . . Under its assignment, statistical requirements of operating, accounting and other departments with respect to maintenance of way and structures, forms are submitted to cover the recapitulation and distribution of material. . . . In collaboration with the Committee on Water Service, an up to date system of Water Service Department forms has been developed in lieu of the present obsolete forms in the Manual. . . . The enactment of the Emergency Transportation Act of 1933 has affected the valuation procedure through amendment of the Valuation Act of the Interstate Commerce Commission. On account of this revision of the Valuation Act, there is a tendency to minimize the future importance of the property records of the carriers which have been inaugurated under the activities of the Valuation Order No. 3. The Depreciation Order, the tentative revised classification, and Valuation Order No. 3 are so closely tied into each other that activities with respect to one should be closely coordinated with the activities of the others if economical handling is to be obtained. . . . Attention is called to the repeal of the recapture clause of the Interstate Commerce Act, and that payments made thereunder have been ordered returned to the carriers involved. . . . The Committee reports progress on its assignment, methods for avoiding duplication of effort and for simplifying and coordinating work under the requirements of the Interstate Commerce Commission.

**Rules and Organization** (E. H. BARNHART, *Chairman*).—For a number of years this Committee has been engaged in the preparation of a Manual of Rules for the Guidance of Employees of the Maintenance of Way Department. Continuing this study, the Committee presents in its current report rules for the maintenance of bridges—masonry and composite structures; rules for the maintenance of telegraph and telephone lines and appurtenances; revised rules on fire protection, all of which are offered for approval. . . . Last year the Committee submitted a report on appropriate titles for Assistant Engineers in all departments. No comments or criticism having been received during the year, the report is now offered for approval as recommended practice.

**Water Service and Sanitation** (R. C. BARDWELL, *Chairman*).—For several years, this Committee has made progress reports on the cause and extent of pitting and corrosion of locomotive boiler tubes and sheets, and has made available a large amount of interesting data on the subject in Vol. 23, 25, 26, and 33 of the Proceedings. The current report contains additional material on this live subject. . . . During the year the Committee has endeavored to summarize the monetary value of the various methods of water treatment, and presents the results of its study in an interesting report. . . . An exceedingly valuable and comprehensive report is that on developments in pipe joints. Historical data on the methods of the transportation of water is presented. Over one hundred types of joints are described and illustrated. . . . This Committee is also concerned with sanitation, and in connection with this phase of its scope, it is giving study to the essentials of mosquito control. A monograph on this topic by the Committee forms a valuable contribution to the report. . . . The Committee has carried on an extended investigation

of disinfectants, fumigants and cleaning materials. The Committee presents an outline of correlated purposes for which disinfectants, fumigants, deodorants, and cleaning materials are used on railways, on which it proposes to render a detailed report in the future.

**Yards and Terminals** (M. J. J. HARRISON, *Chairman*).—Under Revision of Manual, the Committee proposes changes of specified items of the section of the Manual covering Freight Yards; also, changes in the Rules for the Location, Maintenance, Operation and Testing of Railway Track Scales. A definition of a standard test of a railway track scale is offered for approval. . . . On the subject, grain elevator storage yards and plant tracks, the Committee presents an analysis of replies received to a questionnaire, which forms the basis of its report. The general types of grain elevators are described, and a statement showing characteristics of 47 grain elevators served by railroads is included in the report. Layouts of grain elevator storage yards and plant tracks are given. . . . In its report on Hump Yards, submitted a year ago, the Committee presented information on what is termed the graphic method to be used in designing gradients in connection with the application of car retarders to hump yard operation. Two graphic methods were described, "A" and "B". The current report contains a further discussion concerning application under graphic method "B". . . . Proposed Specifications for the Manufacture and Installation of Motor Truck, Built-in, Self-Contained and Portable Scales for Railway Service are submitted as information and criticism. They are intended to supersede corresponding specifications in the Manual which are recommended be withdrawn. . . . The customary bibliography on subjects pertaining to Yards and Terminals appearing in current periodicals is an interesting and valuable feature of the report. . . . Study has been given during the year to the subject, the expediting of freight car movements through yards. The Committee has restricted its first progress report to a generalization of the subject with the intention of carrying its study to more specific details.

**Iron and Steel Structures** (A. R. WILSON, *Chairman*).—The present report consists of a complete revision of the Specifications for Steel Railway Bridges, for fixed spans not exceeding 400 feet in length. This monumental work of revision has engaged the intensive study of the Committee for a period of four or five years. The first specification was adopted in 1903; revisions were made in 1904, 1905, 1906, 1910, 1920, 1923, 1925, 1931. . . . The personnel of the Committee comprises leading railway Bridge Engineers of this and foreign countries, members of faculties of Universities, and bridge fabricators. As an indication of the value of these specifications it is of interest to note that they have been translated into the Spanish language and published under the auspices of the Argentine Republic government. The introductory to the translation stated that these specifications exemplify the best modern practice for steel railway bridges. This document may be considered one of the outstanding achievements of the Association.

**Economics of Railway Location** (F. R. LAYNG, *Chairman*).—This Committee has been requested to give a definition for "Rise-and-Fall," and in compliance with that instruction, quotes the definitions given by a number of authorities, and recommends that the following definition be adopted: " 'Rise-and-Fall' is the sum of vertical ascents in rising from a starting point or level to a summit and returning to same point or level, inclusive of all grades on the profile between any two points or termini."

**Electricity** (W. M. VANDERSLUIS, *Chairman*).—It is the function of this Committee to keep the AREA members informed of the activities of the Electrical Section, and of developments in the application of electricity to railway service. A synopsis is given of the current reports made to the Electrical Section. Among the reports of special interest to Maintenance of Way Engineers are reports on electric heating, application of different types of motors, protection of railroad equipment from danger of fire caused by electric sparks during the transfer of inflammable liquids, illumination, design of indoor and

outdoor substations, and application of corrosion-resisting materials to railroad electrical construction.

**Wood Preservation** (F. C. SHEPHERD, *Chairman*).—For the purpose of harmonizing the AREA specifications for Creosote with those of the ASTM and the AWP, certain revisions are proposed. A number of other changes in the chapter on Wood Preservation are presented for approval. . . . The presentation of service test records of treated ties has been continued. Reports covering special test tracks on a number of roads are presented. . . . The Committee has continued its contact with the Chemical Warfare Service of the U. S. Army in the study of piling used for marine construction. A large amount of valuable information on marine borers is included in the current report. . . . Specifications for Treatment of Air-Seasoned Douglas Fir are presented for approval. . . . The Committee has continued its study of termites and presents interesting material on this subject. . . . A timely and valuable report is that relating to the loss of preservative in treated ties in track due to use of oil-burning weed destroyers. . . . The Committee presents in an interesting manner report on methods of protection of treated materials in the field. . . . A notable report is that relating to service test records of structural timber, including piling. The report includes an interesting tabulation on service test records of structural timber giving outstanding service.

**Uniform General Contract Forms** (F. L. NICHOLSON, *Chairman*).—The Form of Agreement for the Purchase of Electrical Energy in Large Volume (such as required for traction purposes), submitted heretofore in preliminary form, has been revised in the light of the comments and suggestions received, and the draft of the completed form is now presented for approval as recommended practice. . . . A Form of Conveyance of Title Granting the Right to Construct and Maintain Buildings over Railway Property has been formulated and is offered for consideration and comments. . . . On the subjects, Form of Agreement for Pipe Lines Crossing Under Railway Tracks, and Form of Agreement for Use of Railway Property by Pipe Lines Paralleling Railway, with special reference to pipe lines carrying high pressure inflammable oils or gas—the Committee decided that one form could be prepared to cover both assignments, and accordingly has prepared a form in collaboration with other committees concerned and with a special committee of the American Petroleum Institute, and now presents the form for approval as recommended practice. . . . A Form of Agreement with Public Authorities for Highway Grade Crossing Elimination or Separation is submitted for information and discussion.

**Economics of Railway Operation** (J. E. TEAL, *Chairman*).—Under the title, economic effect of the new 131-lb. RE rail section on the cost of operation, as compared with the 130-lb. RE section, the Committee has presented an exhaustive analysis to determine whether or not an improvement has been secured. The report is sub-divided into life of rail; effect of wear on life of rail; effect of carbon content upon the life of rail; effect of amount of rolling and rapidity of cooling upon life of rail; effect of stiffness, of width of head; estimated life of the two rail sections; material cost of the two sections; effect of rail upon track maintenance, and upon equipment; economies in cost of tie renewals per mile of main track; effect of rail upon train operation; recapitulation, and under conclusions the Committee states the 131-lb. RE rail section as compared with the 130-lb. section is an improvement by reason of its increased girder strength, resulting in better riding track, with less damage to equipment and track and a consequent lower operating cost; the improvement in the design of the rail head should result in better quality of metal, thus prolonging rail life and decreasing possibility of accidents due to breakage; these factors therefore should result in an appreciable saving without materially increasing investment. . . . A valuable report is submitted on the capacity of steam locomotives (a supplement to the 1933 report); and a preliminary comparison of freight train and yard switching performance for the purpose of noting the effect of operating heavy trains upon yard performance. The report contains numerous diagrams and tables. . . . Another able report is

presented by the Committee on the effect of volume of traffic on railway operating expense, supplemented with a series of tables and diagrams.

**Economics of Railway Labor** (LEM ADAMS, *Chairman*).—A review of the report on methods of reducing work-train service, and economies in maintenance of way expenses effected thereby, discloses that intensive studies has been given this subject by the Committee. As a result of its study, the Committee concludes that maintenance of way operations should be carefully planned to reduce the number of work-trains required; by so programming work as to permit it to be done in consecutive order and eliminate duplicate movements; by utilizing spare time of light extra and local trains; by having a thorough understanding by all concerned in the transportation and maintenance departments regarding work to be done and time required to do it; by insuring that locomotives assigned have sufficient power to handle the work; by loading materials in suitable cars; by selection of proper type of cranes for loading and unloading rail and having a properly organized gang experienced in the kind of work being done; by lining up work to be done in consecutive order to avoid backup movements and having sufficient work for a full day's work-train service; by the extended use of motor cars to handle men and materials; by the use of self-propelled equipment wherever suitable by further development and use of off-track equipment. . . . Another excellent report is that of programming of bridge and building work. Suitable forms for accomplishing the desired object are presented. . . . One of the subjects to which this Committee has addressed itself in years past is that of handling railway labor. In one of its earlier reports, typical plans for housing labor were presented. That report contained typical plans for the construction of camp or outfit cars; these plans have been beneficial in bringing about an improvement in the sanitation and comfort of outfit cars for floating gangs. Revision of these earlier plans has been assigned to the Committee, and in line with its instructions, the Committee has presented typical plans for the construction of foreman's car; kitchen and dining car; recreation car; sleeping car, and water and fuel car, and recommends that living conditions of outfit cars be made as comfortable and sanitary in accordance with these general plans as economic conditions permit.

**Shops and Locomotive Terminals** (J. M. METCALF, *Chairman*).—At the last annual meeting, a series of conclusions with reference to turntables were presented for approval and which were adopted, with the exception of one conclusion, No. 3, which referred to the method of installation for power-operated turntables. Further study has been given to this feature during the year, and the Committee now presents a revised conclusion for approval. . . . A new subject was assigned to this Committee for study and report, entitled, power plants. This assignment has been interpreted to mean power plant operation, maintenance and recommended capacity at important locations. An interesting report has been prepared along these lines. . . . A valuable contribution is presented on wheel-removing equipment for engine houses. The report deals with the evolution of drop-pit equipment, drop tables, special points of advantage, general requirements, and selection of drop table. . . . Based on replies to a questionnaire, a valuable report has been formulated on the subject of car paint shops.

**Rivers and Harbors** (W. C. SWARTOUT, *Chairman*).—Additional definitions of terms are presented for criticism. . . . Detailed specifications for the construction of the several types of river bank protection in common use have been formulated and are submitted as information. . . . A valuable report is that describing and illustrating the different forms of protecting wharves by means of fenders. . . . An interesting contribution to the knowledge of the subject is the report on coal and ore piers on the Atlantic and Pacific Coasts and ore docks on the Great Lakes, including description of foundations, facilities and capacities. Reference is made to articles in engineering magazines descriptive of many of these coal and ore docks. . . . The Committee calls attention to the excessive clearance requirements for bridges spanning inland streams which are considered navigable, and states

it is collecting information for use in reporting a formula which can be used as a guide to a proper solution of problems of this character. . . . Intensive study has been given to the subject of cost to the railways for the construction, maintenance and operation of bridges over navigable waterways. The statutes of the United States applicable to navigation and navigable waterways are quoted. From its study of the subject the Committee has set forth a series of principles that in its judgment are equitable and that should govern in providing funds for the construction, maintenance and operation of bridges, including approaches thereto, over navigable waterways.

**Standardization** (J. C. IRWIN, *Chairman*).—It is the function of this Committee to encourage the use of AREA recommended practice, to propose to the Board of Direction projects for national standardization, to maintain contact with standardization bodies, and to keep the Association informed on important matters developed by such contact. The report describes the contact established during the year with the staff of the Federal Coordinator of Transportation, specifically with the Section of Purchases. . . . Subjects recommended for national standardization are listed and their present status set forth. . . . Developments in American Standards Association are reported on, including the plan of transferring to the ASA most of the work heretofore handled by the National Bureau of Standards in the sphere of simplification, commercial standards, safety codes and building codes. . . . A brief memorandum regarding the Canadian Engineering Standards Association activities is included in the report. . . . The standards approved by the ASA in the period September 1, 1932 to September 1, 1933, are listed. . . . The technical projects on which the railway associations are cooperating conclude the report.

**Waterproofing of Railway Structures** (J. A. LAHMER, *Chairman*).—Principles governing the use of waterproofing or damproofing of railway structures are submitted as information. . . . A year ago, the Committee presented a specification for membrane waterproofing. This specification is now resubmitted for approval and insertion in the Manual. Only a few minor changes have been made in the previous version for the purpose of simplification and the elimination of a minor inconsistencies.

**Maintenance of Way Work Equipment** (C. R. KNOWLES, *Chairman*). The Committee submits an interesting report on the adaptability of air and electric driven tools in maintenance of way work, the current contribution dealing principally with track grinders. Various types are illustrated in the report. . . . An exhaustive report on snow-melting devices was presented last year; the current report supplements the information previously submitted. The Committee concludes that under proper conditions, snow-melting devices are an aid in facilitating train operation and reducing maintenance expenses. . . . Supplementing its report of last year on the use and adaptability of track type tractors in maintenance of way work, the current report describes specific operations of such tractors used in conjunction with certain specially designed attachments, which adapt the machine to various uses. The report contains some interesting illustrations. A scoring sheet is shown for the purpose of providing a basis for the logical and systematic comparison of tractors of various makes and aid in the selection of a particular machine for purchase. . . . A most practical and interesting report is that on the use of weed destroying equipment, including horse-drawn and power mowers operating both on and off the track. A table indicating weed destroying equipment and cost data for operation is included in the report. Various types of weed burners are illustrated. . . . A comprehensive report is submitted on track welding equipment, both oxy-acetylene and electric arc. The two types are described and illustrated. . . . The Committee offers another valuable report on the use and maintenance of paint spraying equipment, with outline of typical organization for various classes of work. An interesting supplement to this report is a monograph on the hazard of spray painting. . . . The report concludes with an additional contribution to its previous report on the organization for the use and maintenance of ballast cleaning machines and con-

ditions under which each particular type may be used. Developments in this field since the former report was rendered are reported on and the new types of cleaning units described.

**Clearances** (A. R. WILSON, *Chairman*).—An outline diagram of proposed ARA standard box car is submitted for approval. This clearance diagram continues the series that the Committee will present from time to time supplementing those previously adopted. It is planned to eventually assemble all clearance diagrams in one place in the Manual for the guidance of those having need for this important information.

**Stresses in Railroad Track** (DR. A. N. TALBOT, *Chairman*).—The sixth progress report contains chapters on laboratory tests of Rail-Joints, tests of Rail-Joints on the Pennsylvania Railroad, tests of Rail-Joints on the Chesapeake and Ohio Railway, track depression and rail stresses in tests on the Chesapeake & Ohio Railway, tests of GEO track on the Missouri Pacific Railroad, discussion of tests of Rail-Joints and discussion of tests of track. . . . The work reported involves two general lines of tests, (1) a continuation of the investigation of the rail-joint reported in the Fifth Progress Report, and (2) a study of the general properties and quality of track as related to the stiffness of the rail support and to the uniformity or variability of the play or vertical movement between rail and tie and between tie and its support on the ballast bed upon the application of load. The investigation of the rail-joint has included laboratory tests of several forms of rail-joints to determine characteristics of their action in resisting the bending moments produced by loads, both through an analytical treatment and by a study of the tests themselves. Study has been given to the action of a joint bar as a girder, to the magnitude and position of the supporting reactions at the bottom fishing surface, and to the play between rail and bar (small or large) by reason of lack of fit, and to the corresponding increase in the deflection of the rail-joint. The conditions of the track which affect the development of moment in the rail-joint and the corresponding effectiveness of the joint as a continuation of the rail as a girder have been considered. The angle bar and the symmetrical type of bar have been compared in relation to their usefulness as joint bars. Tests were made on rail-joints in track which have related their behavior in track to the information obtained in the laboratory tests. An important set of tests on rail-joints in track was made with an electric locomotive running at various speeds up to 90 miles per hour. These tests gave information on the stresses developed at the higher speeds as compared with those found at low speeds. The changes in tension in the joint bolts during the passage of the locomotive wheels were also measured. The effect of various conditions of the joint itself, such as tightness or looseness of bolts, fit or play between rail and joint bar, and condition of tie support, was also investigated.

The President:—You have heard the reports of the Secretary and Treasurer. What is your pleasure?

Mr. D. J. Brumley (Illinois Central):—I move the approval of the reports of the Secretary and Treasurer.

Mr. Louis Yager (Northern Pacific):—I second the motion.

The President:—It has been moved and seconded that the reports of the Secretary and Treasurer be approved. All in favor say "aye"; contrary. It is carried and so ordered.

This thirteenth day of March is an occasion that our Secretary no doubt always remembers. He has been with us for thirty-five years, about thirty years of which he has been filling the position of Secretary. Today he is seventy-four years of age. I will ask the convention to stand in his honor.

The President:—The privileges of the floor are extended to visiting railway officials who are not members of the Association, to professors in colleges, as well as any members of the Federal Coordinator's staff that may be present, and they are invited to take part in the discussion of subjects in which they are interested.

The Chair would especially urge the newer and younger members to actively participate in the discussion on the floor. As the older members retire, it is necessary that we have the younger element come to the front and fill up the gap. These new members undoubtedly have views and opinions on the subjects that will be presented, and we would be glad to have their experience and comments.

In the Secretary's report reference was made to a number of deceased members. I will ask that we stand in silence for a moment in their respect.

(The convention arose and stood in silent tribute to the memories of the deceased members.)

The next order of business is the consideration and action of the Standing and Special Committees. As the Committees are called, they will please come to the platform. The first is the Committee on Uniform General Contract Forms. The Committee will please come forward.

The report will be presented by Mr. F. L. Nicholson, Chief Engineer, Norfolk Southern Railway, the Chairman of the Committee.

(For Report, see pp. 309-332.)

The President:—The second report is that of the Committee on Yards and Terminals. Mr. M. J. J. Harrison, General Scale Inspector, Pennsylvania Railroad, is Chairman of the Committee and will please present the report.

(For Report, see pp. 419-472.)

The President:—The next report is that of the Committee on Rules and Organization. Mr. E. H. Barnhart, Assistant Division Engineer, Baltimore & Ohio Railroad, is Chairman, and will tell you what action is desired.

(For Report, see pp. 521-528.)

The President:—The report of the Committee on Records and Accounts will be presented to you by its Chairman, Mr. C. C. Haire, Engineer of Capital Expenditures, Illinois Central System.

(For Report, see pp. 579-620.)

The President:—Mr. Geo. S. Fanning, Chief Engineer, Erie Railroad, Chairman of the Committee on Roadway, will please present the report to you.

(For Report, see pp. 347-402.)

#### AFTERNOON SESSION

The President:—The first report on this afternoon's program is that of the Special Committee on Clearances. Mr. A. R. Wilson, Engineer Bridges and Buildings, Pennsylvania Railroad, is Chairman of the Committee.

(For Report, see page 675.)

The President:—The next report is that of the Committee on Ballast. In the absence of the Chairman and Vice-Chairman, I will ask Mr. A. D. Kennedy, Assistant Engineer of the Santa Fe, to present the report.

(For Report, see pp. 663-770.)

The President:—The report of the Committee on Track will be handled by Mr. C. J. Geyer, Assistant to Vice-President, Chesapeake & Ohio Railway.

(For Report, see pp. 923-955.)

Vice-President John E. Armstrong:—The report of the Buildings Committee will be presented by its Chairman, Mr. G. A. Rodman, General Supervisor Bridges and Building, New York, New Haven & Hartford Railroad.

(For Report, see pp. 529-559.)

Vice-President John E. Armstrong:—The next report is that of the Committee on Shops and Locomotive Terminals. Mr. J. M. Metcalf, Assistant Chief Engineer, Missouri-Kansas-Texas Lines, is Chairman of the Committee.

(For Report, see pp. 403-417.)

Vice-President John E. Armstrong:—Our next report is the Committee on Maintenance of Way Work Equipment. Mr. C. R. Knowles, Superintendent Water Service, Illinois Central System, is Chairman, and will present the report to you.

(For Report, see pp. 473-520.)

The President:—The report of the Committee on Waterproofing Railway Structures will be presented by its Chairman, Mr. J. A. Lahmer, Senior Assistant Engineer, Missouri Pacific Railroad.

(For Report, see pp. 699-712.)

## EVENING SESSION

The President:—The first report this evening will be that of the Committee on Rail. Mr. Earl Stimson, Chief Engineer Maintenance, Baltimore & Ohio Railroad, is Chairman, and will please present the report.

(For Report, see pp. 829-878.)

The President:—The next report is that of the Special Committee on Stresses in Railroad Track. The report will be presented by Dr. A. N. Talbot, Professor Emeritus of the University of Illinois, Chairman. Dr. Talbot's report will be accompanied with lantern slides.

(For Report, see Bulletin 358.)

## WEDNESDAY, MARCH 14, 1934

### MORNING SESSION

The President:—The first report this morning is that of the Committee on Ties. Mr. W. J. Burton, Assistant to Chief Engineer, Missouri Pacific Railroad, is Chairman, and will tell you what action is desired on this report.

(For Report, see pp. 779-828.)

The President:—The next Committee to report is that on Wood Preservation. Mr. F. C. Shepherd, Consulting Engineer of the Boston & Maine, is Chairman.

(For Report, see pp. 713-777.)

The President:—The Committee on Water Service and Sanitation report will be presented to you by the Chairman, Mr. R. C. Bardwell, Superintendent Water Supply, Chesapeake & Ohio Railway.

(For Report, see pp. 621-643.)

Vice-President John E. Armstrong:—The report of Committee X—Signals and Interlocking will be presented to you by Mr. P. M. Gault, Signal Engineer, Missouri Pacific Lines, the Chairman.

(For Report, see pp. 333-341.)

Vice-President John E. Armstrong:—The next Committee to report is Committee XVIII—Electricity. Mr. W. M. Vandersluis, General Superintendent Telegraph and Signals, Illinois Central System, is Chairman, and will tell you what action is desired by the convention.

(For Report, see pp. 343-345.)

Vice-President John E. Armstrong:—The report of the Committee on Wooden Bridges and Trestles will be presented to you by its Chairman, Col. H. Austill, Bridge Engineer, Mobile & Ohio Railroad.

(For Report, see pp. 997-1009.)

The President:—The report of the Committee on Masonry will be presented by its Chairman, Mr. Meyer Hirschthal, Concrete Engineer, Delaware, Lackawanna & Western Railroad.

(For Report, see pp. 957-996.)

#### AFTERNOON SESSION

The President:—The report of Committee IX—Grade Crossings will be presented to you by its Chairman, Mr. J. G. Brennan, Engineer of Grade Crossings, New York Central.

(For Report, see pp. 561-577.)

The President:—Committee XXV—Rivers and Harbors will be presented by its Chairman, Mr. W. C. Swartout, Assistant Engineer, Missouri Pacific Railroad.

(For Report, see pp. 677-697.)

The President:—The next report is that of the Committee on Iron and Steel Structures. Mr. A. R. Wilson, Engineer Bridges and Buildings of the Pennsylvania Railroad, is Chairman, and will tell you about the report.

(For Report, see pp. 1011-1064.)

Vice-President Robert H. Ford:—The next report is that of the Committee on Economics of Railway Location. Mr. F. R. Layng, Chief Engineer, Bessemer & Lake Erie Railroad, is Chairman.

(For Report, see pp. 671-674.)

Vice-President Robert H. Ford:—The next report is that of the Committee on Economics of Railway Operation. Mr. J. E. Teal, Special Engineer—Operation, Chesapeake & Ohio Railway, is Chairman, and will tell you what action is desired by the convention.

(For Report, see pp. 879-922.)

Vice-President Robert H. Ford:—The report of the Committee on Economics of Railway Labor will be presented to you by its Chairman, Mr. Lem Adams, Chief Engineer, Oxweld Railroad Service Company.

(For Report, see pp. 645-662.)

Vice-President Robert H. Ford:—The last report this afternoon is that on Standardization. Mr. J. C. Irwin, Valuation Engineer, Boston & Albany Railroad, is Chairman, and will give you a synopsis of the report.

(For Report, see pp. 1065-1077.)

The President:—This completes the consideration of Committee reports.

The next order of business is New Business. Has anyone anything to offer under that heading?

Mr. Edwin F. Wendt (Consulting Engineer):—I desire to offer a resolution.

"The American Railway Engineering Association, in convention assembled, expresses its hearty appreciation to Dr. A. A. Potter, Dean of Engineering, Purdue University, for his most excellent and constructive address at the luncheon of the Association on Wednesday, March 14."

I move the adoption of this resolution.

The President:—You have heard the resolution. All those in favor will say "aye"; contrary. It is carried.

Is there any further new business? The result of the attendance this year is 510 members and 198 visitors, a total of 708, as against 395 members and 209 visitors, a total of 604, in 1933.

If there is no further new business, the Secretary will announce the result of the election of officers for the ensuing year.

Secretary E. H. Fritch: Report of the Tellers. "We, the Committee of Tellers, report the following as the result of the count of the ballots:

*For President:*

|                         |           |
|-------------------------|-----------|
| John E. Armstrong ..... | 937 votes |
|-------------------------|-----------|

*For Vice-President:*

|                     |           |
|---------------------|-----------|
| A. R. Wilson .....  | 931 votes |
| S. S. Roberts ..... | 1 vote    |

*For Secretary:*

|                    |           |
|--------------------|-----------|
| E. H. Fritch ..... | 937 votes |
|--------------------|-----------|

*For Treasurer:*

|                    |           |
|--------------------|-----------|
| A. F. Blaess ..... | 927 votes |
|--------------------|-----------|

*For Directors (Three to be elected):*

|                      |           |
|----------------------|-----------|
| R. C. Bardwell ..... | 395 votes |
| W. J. Burton .....   | 368 votes |
| E. L. Crugar .....   | 355 votes |
| F. L. C. Bond .....  | 350 votes |
| W. H. Penfield ..... | 336 votes |
| J. A. Peabody .....  | 298 votes |
| C. C. Williams ..... | 281 votes |
| R. S. Belcher .....  | 254 votes |
| C. A. Wilson .....   | 186 votes |

(The three elected are:—R. C. Bardwell, W. J. Burton, E. L. Crugar.)

*For Members Nominating Committee (Five to be elected):*

|                      |           |
|----------------------|-----------|
| W. S. Burnett .....  | 554 votes |
| E. H. Barnhart ..... | 538 votes |
| H. A. Dixon .....    | 526 votes |
| A. A. Miller .....   | 521 votes |
| W. A. Murray .....   | 485 votes |
| Robert Faries .....  | 468 votes |
| J. M. Farrin .....   | 450 votes |
| Wm. Michel .....     | 416 votes |
| C. B. Stanton .....  | 395 votes |
| John Foley .....     | 252 votes |
| J. A. Heaman .....   | 1 vote    |

(The five elected are:—W. S. Burnett, E. H. Barnhart, H. A. Dixon, A. A. Miller, W. A. Murray.)

Signed by the Committee of Tellers, Ben B. Shaw, Chairman.

The President:—It is customary to present to the outgoing Past-President a medalion as a token of our esteem and regard. Mr. W. D. Faucette is the Senior Past-President and is the recipient of the medal this year. Mr. Faucette is unavoidably absent and, with your approval, it will be presented to him at an opportune time.

Mr. J. C. Irwin (Boston & Albany):—President Wiltsee, in times of stress a strong man always arises with the ability to overcome all obstacles.

When you were started by this Association on the direct path to the presidency, it was realized that you had the qualities to overcome obstacles and deliver the goods. During the year of your administration there have been very many unusual problems, but you have met them in every case with prompt action, sound judgment and outstanding ability.

I have the honor, Sir, to act for the Association in presenting to you, in the form of a resolution and permanent record, this plaque as a testimonial from the Association in recognition of your distinguished services to the Association. I now present this resolution, and, in presenting it, I also second the resolution as follows:

“The American Railway Engineering Association records its grateful appreciation to WILLIAM P. WILTSEE for valuable services rendered as President in 1933–34. He contributed freely and generously of his time and ability to the solution of important problems arising during his term as President, and his sound judgment and high-minded conception of his responsibility materially enhanced the prestige and achievement of the Association.”

Mr. Wiltsee, we present this to you (Applause).

I call for a rising vote.

(The audience arose and applauded.)

Mr. J. C. Irwin:—President Wiltsee, that is the rising vote approving the resolution.

The President:—Mr. Irwin and Gentlemen: I thank you very much. I do not have words to express my feelings in this matter. It is a time and a place where a man realizes whether or not he has been a failure. Whatever success there may have been during this year I attribute very much to our Committees and to our Board of Direction who have assisted me in every way, in granting me such powers as they did, and I could not help but carry on the work successfully with such cooperation.

Thank you, gentlemen (Applause).

If there is no further business before the meeting, the Chair will ask Past-Presidents Brumley and Fairbairn to escort the President-Elect to the platform.

(President-Elect Armstrong was escorted to the platform. The audience arose and applauded.)

The President:—Mr. Armstrong, I want to congratulate you on your election to the important office of President of this Association. I am sure you will have the hearty cooperation of all the officers and Committee Chairmen and that you will serve them well and have a successful year.

I take pleasure in turning over this gavel to you, Sir, and congratulate you (Applause.)

(President-Elect Armstrong assumed the Chair.)

The President:—Mr. Wiltsee and Fellow-Members: I greatly appreciate the confidence that you have shown in me in advancing me to this position at this time.

The past few years have not been easy years for this Association, and the coming year may prove to be, in many respects, equally difficult. I am looking forward, however, without a qualm. With such support as the officers, Directors, Committees and

THE  
AMERICAN RAILWAY ENGINEERING ASSOCIATION  
RECORDS ITS GRATEFUL APPRECIATION  
TO  
WILLIAM P. WILTSEE  
FOR  
VALUABLE SERVICES RENDERED AS  
PRESIDENT  
IN  
1933-1934  
HE CONTRIBUTED FREELY AND GENEROUSLY  
OF HIS TIME AND ABILITY  
TO THE SOLUTION OF IMPORTANT PROBLEMS

AND  
HIS SOUND JUDGMENT AND HIGH-MINDED CONCEPTION  
OF HIS  
RESPONSIBILITY MATERIALLY ENHANCED THE PRESTIGE  
AND ACHIEVEMENT OF THE ASSOCIATION

members of this Association have so continuously and freely given in the past, we have no reason to fear for the future.

I am deeply conscious of the honor you have conferred upon me in advancing me to this high position, and I shall endeavor to merit this honor by serving you as you would be served, and doing everything in my power to maintain the prestige of the American Railway Engineering Association. Thank you (Applause).

Is there any further business to come before this meeting? If not, I declare the Thirty-fifth Annual Convention of the American Railway Engineering Association adjourned.

A handwritten signature in cursive script, reading "E. N. Fritch". The signature is written in dark ink and is positioned above the printed name "Secretary.".

*Secretary.*

## RESEARCH AS APPLIED TO RAILROADING

By Dr. A. A. POTTER, Dean of Engineering and Director Engineering  
Experiment Station, Purdue University; Past-President A.S.M.E.

The railroads of this country deserve major credit for our national unity; great distances separate the political units of our government and its solidarity depends upon effective, dependable, safe and adequate transportation facilities. A democratic government, like the U.S.A., could not have been maintained 200 years ago; no doubt the locomotive did more to keep our forty-eight states together than has all special legislation in Washington and at the State capitals. The large geographic area of this country, the absence of economic barriers between our states and the resulting free interchange of goods and services, make transportation of vital importance to our commerce and industry.

The past record of American railroading needs no defense and its indispensability in connection with our future social and economic progress cannot be questioned. Railroad management has been fully appreciative of the fact that operation and maintenance of railway equipment require constant study and vigilance. During the period from 1923 to 1933 inclusive the American Railway Association has expended for research, experimentation, testing and standardization nearly six and three-quarter million dollars; additional sums, the total of which it is difficult to estimate, have been expended for testing, development and research by individual railroads and by manufacturers of equipment. However, one hears too frequently implications that the railroad companies have stood still and have neglected to make full use of new science to insure their future programs with a degree of certainty. The February 1934 issue of *Mining and Metallurgy*, in discussing the publication of the American Railway Association entitled "The American Railroad in Laboratory," states that the railroads have carried on experimentation but not research, adding that "the book is a mute evidence of the fact that its sponsors have no true conception of scientific research in its modern aspect."

The questions before us then are: first, what is research; second, are the railroads constantly alert to the new scientific developments which come from the outside; and third, how can railroading make greater use of basic scientific knowledge to improve service, reduce costs and increase earnings?

What is research? Research is a fact-finding agency. It has as its aim the orderly search for something hitherto unknown by the employment of facts. To most people research means search for new knowledge in the fields of biology, physics, chemistry or in applied science such as engineering, when this involves the use of test tubes, delicate instruments and special machines under fully isolated conditions.

The search for truth by the fact-finding method, however, applies to human as well as to material problems; to advertising, marketing and personnel matters as well as to development, design, manufacturing, maintenance and service; to psychology, economics, sociology, and politics as well as to biology, physics, chemistry and engineering. Fact-finding methods and not merely opinions should prove helpful in solving problems of finance and government as well as questions pertaining to physical sciences and technology. No clear-cut differentiation can be drawn between pure scientific and engineering research, although the latter is generally concerned with results of immediate economic value. The difference between development and research is also far from distinct. Development usually follows basic research if a marketable product is the aim, but development must involve fact-finding technique through experimentation and testing.

---

Address before the American Railway Engineering Association, March 14, 1934.

All types of scientific research, whether pure or applied, require testing and experimentation.

Thus it matters little whether the fact-finding activities of the railroads are called research or development or testing or experimentation, provided they are useful in securing facts to guide decisions with reference to equipment purchase and maintenance as well as for the improvement of operation and service. It is not clear, however, whether the railroads have utilized research to explore new opportunities or were merely satisfied to employ experimentation and testing to improve present devices and methods. An analysis of the railroad research program during the past 40 years leads one to question as to whether the railroads have given sufficient attention to new ideas and have been satisfied to devote their creative efforts to the improvement of existing equipment. Statements have even been made that the present condition of the railroads would have been much better had they explored absolutely new paths and had they watched more carefully development from the outside.

Accordingly, it may be well to appraise the activities of the fact-finding agencies in connection with railroading. These include: Equipment manufacturers, individual railroads and the American Railway Association.

The manufacturing industry of this country supplies to the railroads the materials, structures and equipment. Most of the equipment manufacturers who serve the railroads also sell materials and equipment to other industries; thus the gains which these equipment companies have secured through research have been transmitted to the railroads as well as to the other customers of the manufacturing industry. The equipment manufacturers have greatly contributed to the increased output of American railroads per dollar of investment and per employee by improvements in plant. While some of the leading European railroads build two-thirds or more of their locomotives in their own shops, the majority of American locomotives have been built by manufacturing companies which have specialized in locomotive design and construction. The marked increase during the past decade in the power output per driving axle and the reduction during the same period of about twenty per cent in fuel consumption per passenger-train car mile and of nearly thirty per cent in fuel per ton-mile of freight hauled are an indication of the progress made by American locomotive builders and by manufacturers of locomotive auxiliary and accessory equipment. Paralleling the improvements in steam locomotives one finds great strides in electric locomotive design as well as in internal-combustion-driven rail cars and Diesel-electric locomotives for special service. Apparently the manufacturers of car equipment are also appreciative of the contributions of research and are saving car weight by the use of welded steel construction and light weight materials. Manufacturers of equipment and supplies have also expended large sums to insure improved air brakes, better car cushioning, more effective bearings and superior lubrication. Time will not permit to discuss in detail the improvements made by manufacturers individually and cooperatively in car trucks and parts, car wheels, automatic couplers, draft gears, or in special equipment for locomotive repairs and for the upkeep of tracks and structures, or in signaling; these are all greatly contributing to the plant efficiency and safety of travel, while reducing train delays.

The contributions of the equipment manufacturers to new knowledge are many and most pertinent to advancement in railroading, but there is a feeling in certain quarters that research and development by equipment companies are guided largely by their own ideas of the railroads' needs instead of benefiting by their customers' definite recommendation of their requirements. Statements have also been made that equipment manufacturers devote more energy to the pointing out of faults in each other's products than to the improvement of their own; also that railroads consider competition between manu-

facturers of equipment as sufficient guarantee of a superior product. To what extent these statements are true is difficult to answer, but a closer coordination of the research activities of the equipment companies and those of the railroads should aid in avoiding the above-mentioned practices, if they exist.

There is apparently no complete published record of the testing and other research facilities of individual railroads. I do know that the larger railroads do not accept new designs of equipment without special tests, unless such improvements have been approved by the American Railway Association. Most railroads maintain their own test department and have sufficient laboratory facilities for physical and chemical tests. The laboratories of the Pennsylvania Railroad at Altoona, the New York Central Laboratory at West Albany, the Santa Fe Test Department at Topeka, and those of other important lines are utilized for carrying on some experimentation of high order as well as testing. Individual railroads should have considerable credit for the recent advance in air-conditioning of passenger cars, pre-cooling of sleeping cars, the use of improved types of bearings, streamlining and light-weight trains, and improved locomotive performance. However, the creative efforts of the individual railroads are evidently not definitely coordinated, resulting in considerable duplication.

Accurate information is available of the contributions of the American Railway Association through its eight divisions, bureaus and special committees. During the past eleven years (1923-1933 inclusive) more than one-half of the fact-finding expenditures of this association, or over three and three-quarter million dollars, were devoted to the Mechanical Division; the major portion of these expenditures was concerned with the investigations pertaining to air brakes, draft gears and automatic train connectors. The Mechanical Division has had a part-time director of research for a number of years, but the other divisions have depended entirely upon committees. Even in the Mechanical Division the part-time director was concerned only with a portion of the fact-finding activities of this Division, the remainder being also directed by committees. While the devotion, industry and ability of the members of these committees cannot be questioned, it is evident that the men who compose the committees of the different divisions are mainly concerned with operation, are only rarely research specialists and are usually too busy with their regular duties to devote the time necessary to direct and to coordinate research. Members of committees are usually selected because of geographical distribution, or availability, and even favoritism has been known to guide their choice rather than specialized knowledge or outstanding research ability. Furthermore, these committees have been usually appointed to handle routine matters, thus leaving the research problem with little if any direction. Then again the committees of the American Railway Association are appointed to remedy existing troubles and are rarely concerned with new problems or novel methods, and are not in a position to keep the railroads fully informed of developments which take place outside of railroading. Apparently, the American Railway Association coordinates the research activities in railroading only to some extent but not entirely. While the present part-time director is in touch with some of the mechanical phases of railway research, he has nothing to do in coordinating the fact-finding activities of the other divisions of the American Railway Association, of the individual railroads or of the equipment manufacturers.

Great credit should be given to the Engineering Division of the American Railway Association for the present standard rail sections and for basic investigations on rails, grade crossings, preservative treatment of ties, transverse fissure rail failures, and stresses in railroad track. However, a full-time director of research should prove most helpful in bringing about more effective cooperation between all the Divisions and Bureaus of the A.R.A., as well as those of the individual railroads. Such a director, if supplied with

an adequate and capable staff, may also be able to bring about a closer cooperation between the railroads and the equipment manufacturers, and would supplement their efforts. Centralized and authoritative research direction should prove helpful in encouraging investigations, on a larger scale than is possible with the present committee system, not only in basic science, but also business and social research.

While American railroads must be credited with experimentation, standardization and practical research of a high order, which has resulted in service, the quality of which no other railroad system in the world equals, it is the opinion of those who are keenly interested in the future of American railroading that even greater accomplishments might be possible if the railroad industry gave greater attention to basic scientific and business research, under competent centralized direction, and mutually supported by all the railroads of this country.

Effective centralized direction requires a director, assisted by a trained research staff, whose only duty is to undertake new problems for the benefit of all of the railroads of the country. This research should be carried on in a laboratory centrally located. The campus of an engineering college may prove a suitable place for building such a laboratory, as it would then be in an atmosphere which is sympathetic to research. The central research laboratory at an educational institution may prove also advantageous to the railroads from a financial standpoint, as to a considerable extent the facilities of the engineering college in staff, laboratory equipment and library could be utilized. The U.S. Forest Products Laboratory at the University of Wisconsin and the Tanner's Laboratory at the University of Cincinnati are examples of centralized research laboratories at educational institutions.

A central research laboratory under competent direction would not invade the field of the individual railroad test department and should supplement the laboratories of equipment companies. Such centralized direction would, however, definitely correlate all of the valuable research activities of the railroads and of the manufacturers of equipment and should make possible the pursuit of many basic transportation studies which are now difficult to undertake due to the competition between the railroads themselves as well as between the railroads and other modes of transportation. A centralized railroad research agency should also handle patent matters referred to it by railroads. Research to be most productive in revealing new possibilities and in forecasting future trends must be continuous, and cannot be started and stopped on short notice. It takes many years to build up a high-grade research organization and only centralized direction, a central laboratory and a long-time research program may be expected to yield permanent results.

With reference to the types of problems in the interest of railroading, which central research direction may undertake, consideration may well be given to better riding qualities, improved ventilation, greater cleanliness and reduction of noise for passenger cars, elimination of shocks in train handling, mathematical study of springs on vehicles, dynamic balancing of more powerful high-speed motive power, improved prime movers of superior fuel economy, better light-metal alloys, new uses and applications of the findings of science, and experimentation with types of equipment leading to different operating procedure. Central direction of research, if properly financed, may hasten the solution of such problems as the transverse fissure rail failures by extensive studies under controlled conditions. However, research should not be satisfied merely to remedy existing difficulties, but should constantly strive to develop new ideas, better devices and improved methods, while keeping fully informed of the new facts revealed by other industries. Research should back away from things at hand and should take a view of transportation as a whole.

Central direction of research should not limit its activities to science and technology, but should encompass all fact-finding matters, including business and human research problems. Examples of non-technical problems are basis for rates and fares, traffic, railroad financing, wage scales and personnel matters affecting employees, operating cost studies, public relations, with particular reference to favorable impression upon users of service, the coordination of all types of transportation, and similar social and economic problems of interest to railroading.

To be of maximum value, all research activities in railroading must be coordinated with one major objective in view; an objective which keeps constantly in mind the place of the railroad in the transportation fabric of the country. All past studies, technical, social and economic, must be carefully analyzed, and new developments planned to suit the constantly changing conditions, but with the main objective in mind.

The cost of centralized research should be small for sometime, as it will require several years to build up a proper research staff. Existing facilities at some centrally located engineering college could be utilized advantageously, either temporarily or permanently, and the program enlarged as conditions merit greater expenditures. No doubt, the present duplication of research effort and the committee system of supervision involve considerable waste, the elimination of which should result in savings which should be sufficient to start a high-grade central research laboratory for American railroads. There is also a possibility that a proper coordination of all railroad research work would result in less misdirected effort by equipment manufacturers for which the railroads have to pay in the long run.

In the earlier part of my paper I stated that the railroads have expended cooperatively, through the American Railway Association, a total of nearly six and three-quarter million dollars during the past eleven years for research, routine testing and standardization. Of this more than two and one-quarter million were used for investigation of power air brakes, leaving less than four and one-half million dollars for the other types of research, testing and standardization, with railway operating revenues of nearly 53 billion dollars during the period from 1923 to 1933. This means that the railroads have devoted collectively only about one-hundredth of one per cent of their operating income for the creation of new knowledge, as compared with expenditures of one to four per cent for research in the case of progressive industries. The American Telephone and Telegraph Company reports an average annual expenditure of \$8,700,000 for research, even during the past four years of depression, with a gross revenue of only about one billion dollars per year; the Aluminum company of America has been devoting one to four per cent of its gross income for research; and the DuPont, one and one-half to four per cent of its net income; these industries consider expenditures for research as the insurance which their companies must take out in order that their products and services will not only continue to show improvement year by year, but be more adaptable to the changing needs and desires of the people served. Any industry which does not take advantage of new knowledge and is not constantly on the lookout for new developments, is bound to lose in its competition for sales or services.

In advocating more effective centralized research and greater expenditures for the creation of new knowledge, I am not unmindful of the splendid contributions of the American Railway Association, the equipment manufacturers and the individual railroads. So far as they have gone the results have been excellent, but railroad research, particularly of the basic type, has not been carried out on a scale which its importance for railroading deserves; too large a proportion of past research efforts have been directed to old problems and too little to those of the future. Intelligent anticipation of a new problem will often change the course of events and may forestall unfavorable develop-

ments from the outside. A well-balanced and energetic program of basic transportation research will pay big dividends in the practical results secured.

Sir Harold Hartley calls research "the door to to-morrow." Let us hope that greater attention to railroad research will result in a to-morrow which will definitely improve the financial condition of the railroads, will enhance their place in the transportation fabric of this country, and will benefit the public by cheaper, safer and better rail transportation. In the past Government regulation has been responsible at least in part for the failure of railroads to make long-time plans. The many uncertainties which have surrounded railroad financing and management have made it of necessity a hand-to-mouth industry. Let us hope that the forward-looking program of the United States Government will remove some of the past handicaps and will fully justify American railroads in utilizing more research in long-time planning.

In making the above statements I am giving you only my own frank views of the subject of research as applied to railroading and not those of the Committee on Railroads of the Science Advisory Board, of which I have the honor of being a member. This committee in accordance with instructions by Coordinator Eastman, was formed "to co-operate with a committee of railroad executives in an effort to assist the railroads to secure the maximum benefits in utilizing modern science and engineering." It has been my privilege to attend all of the meetings of this joint committee of railroad executives and representatives of the Science Advisory Board, and I can assure you that there is a very fine spirit of helpfulness and of cooperation. The studies of this joint committee have not progressed sufficiently to merit conclusions or recommendations. It is evident, however, that the deliberations thus far have been definitely in the interest of the railroads.

My own long connection with a University, which for over forty years has cooperated most effectively with the railroads of this country and my intimate association with your problems, lead me to assure you of my sincere desire to assist in the return of prosperity to that indispensable and safest means of transportation which you represent.

I feel that research is the "Fountain of Youth" which will aid you in enhancing the place of railroading in the transportation fabric of America. Accordingly, I recommend to you that you make greater use of research in guiding your decisions, that you keep fully informed of new developments outside of your industry, that your experimentation be concerned not merely with improvements in existing equipment, but also with the exploration of new paths, that you take a view of the transportation system as a whole, and that you coordinate all fact-finding activities for rail transportation through a central research laboratory staffed with individuals who are skilled in the creation of new knowledge.

## COMMITTEE REPORTS

**SPECIAL COMMITTEE ON STRESSES IN  
RAILROAD TRACK**

**1933**

# CONTENTS

## I. Introduction

|                                    | PAGE |
|------------------------------------|------|
| 1. Preliminary .....               | 69   |
| 2. Acknowledgment .....            | 70   |
| 3. Previous Progress Reports ..... | 71   |

## II. Laboratory Tests of Rail-Joints

|                                                                                                                |     |
|----------------------------------------------------------------------------------------------------------------|-----|
| 4. The Function and Action of the Rail-Joint .....                                                             | 72  |
| 5. Properties of Rails and Joint Bars .....                                                                    | 75  |
| 6. The Laboratory Tests of Rail-Joints .....                                                                   | 76  |
| 7. General Studies of the Action of Rail-Joints .....                                                          | 79  |
| 7a. N. Y. C. Rail-Joint for 127-lb. N. Y. C. Rail .....                                                        | 79  |
| 7b. Penn. Rail-Joint for 130-lb. P. S. Rail .....                                                              | 80  |
| 7c. Penn. Symmetrical Type Rail-Joint for 130-lb. P. S. Rail .....                                             | 86  |
| 7d. Santa Fe Symmetrical Type Rail-Joint for 130-lb. R. E. Rail .....                                          | 86  |
| 7e. Norfolk and Western Continuous and Head Free Continuous Rail-Joints for<br>130-lb. P. S. Rail .....        | 90  |
| 7f. Muller Rail-Joint for 130-lb. R. E. Rail .....                                                             | 99  |
| 8. Action of a Rail-Joint Under an Advancing Load .....                                                        | 103 |
| 9. Effect of Combinations of Tight and Loose Bolts .....                                                       | 111 |
| 10. The Lateral Springing of the Joint Bars Due to the Application of Bolt Tension<br>and Vertical Loads ..... | 113 |
| 11. Distribution of Stresses over Vertical Section at and near Mid-Length .....                                | 120 |
| 12. Deflection of Rail-Joints and Joint Bars .....                                                             | 127 |

## III. Tests of Rail-Joints on the Pennsylvania Railroad

|                                                                 |     |
|-----------------------------------------------------------------|-----|
| 13. Purpose of Tests and Arrangements Therefor .....            | 130 |
| 14. The Track .....                                             | 131 |
| 15. The Locomotive and Cars .....                               | 132 |
| 16. The Magnetic Strain Gauge and Its Auxiliary Equipment ..... | 133 |
| 17. Conduct of Tests and Reduction of Data .....                | 137 |
| 18. Stresses in Joint Bars .....                                | 141 |
| 19. Moments in Rail-Joints .....                                | 146 |
| 20. Effect of Speed .....                                       | 158 |
| 21. Bolt Tension in the Rail-Joints .....                       | 161 |
| 22. Changes in Bolt Tension under Moving Loads .....            | 165 |

## IV. Tests of Rail-Joints on the Chesapeake and Ohio Railway

|                                                                                                                                            |     |
|--------------------------------------------------------------------------------------------------------------------------------------------|-----|
| 23. The Tests of Rail-Joints on the Chesapeake and Ohio Railway .....                                                                      | 172 |
| 24. The Tests .....                                                                                                                        | 172 |
| 25. Stresses and Moments in Joint Bars at Mid-Section and in Rail Opposite with<br>Heavy Load over Mid-Section .....                       | 174 |
| 26. Stresses and Moments in Joint Bars at Mid-Section and in Rail Opposite with<br>Heavy, Medium and Light Loads over Mid-Section .....    | 183 |
| 27. Moments in Joint Bars at Mid-Section and in Rail Opposite with Heavy Load<br>at Various Positions with Respect to the Rail-Joint ..... | 186 |

|                                                                                                 | PAGE |
|-------------------------------------------------------------------------------------------------|------|
| 28. Stresses and Moments along the Joint Bars with Heavy Load over Mid-Section                  | 188  |
| 29. Vertical Play between Rail and Joint Bar and Deflection of Rail-Joint in<br>66 Inches ..... | 189  |
| 30. Vertical and Lateral Deflection of Joint Bars .....                                         | 194  |

### V. Track Depression and Rail Stresses in Tests on the Chesapeake and Ohio Railway

|                                                                                              |     |
|----------------------------------------------------------------------------------------------|-----|
| 31. Description of the Track .....                                                           | 195 |
| 32. Methods of Testing .....                                                                 | 196 |
| 33. Tests of Track Depression .....                                                          | 197 |
| 34. Elements in the Total Rail Depression .....                                              | 201 |
| 35. Vertical Play or Looseness between Rail and Tie and between Tie and Ballast<br>Bed ..... | 203 |
| 36. Variation in Load Taken by Individual Ties .....                                         | 207 |
| 37. Values of Modulus of Elasticity of Rail-Support $u$ .....                                | 209 |
| 38. Stresses and Moments in Rail .....                                                       | 215 |

### VI. Tests of GEO Track on the Missouri Pacific Railroad

|                                                                  |     |
|------------------------------------------------------------------|-----|
| 39. Description of the GEO Track .....                           | 224 |
| 40. Method of Testing .....                                      | 225 |
| 41. Tests of Track Depression .....                              | 226 |
| 42. Elements in the Total Rail Depression .....                  | 229 |
| 43. Vertical Play or Looseness between Tie and Ballast Bed ..... | 230 |
| 44. Variation in Load Taken by Individual Ties .....             | 232 |
| 45. Values of Modulus of Elasticity of Rail-Support $u$ .....    | 234 |
| 46. Stresses and Moments in Rail .....                           | 238 |

### VII. Discussion of Tests of Rail-Joints

|                                                                                                             |     |
|-------------------------------------------------------------------------------------------------------------|-----|
| 47. The Function and the Action of the Rail-Joint .....                                                     | 244 |
| 48. The Action of Several Forms of Joint Bars .....                                                         | 246 |
| 49. The Position and Magnitude of the Bearing Loads and Reaction Forces Acting<br>upon the Joint Bars ..... | 249 |
| 50. Bolt Tension, Its Function and Action, and the Elastic Lateral Springing of<br>Joint Bars .....         | 253 |
| 51. Fit and Play in Rail-Joint, Vertical Deflection of Joint Bars and of Rail-Joint<br>under Load .....     | 256 |
| 52. The Rail-Joint under an Advancing Load and Effect of Speed on Stresses and<br>Bolt Tension .....        | 257 |
| 53. Miscellaneous Remarks on the Rail-Joint .....                                                           | 262 |
| 1. Shape of the Section .....                                                                               | 262 |
| 2. Fit and Longitudinal Form .....                                                                          | 264 |
| 3. Size and Spacing of Joint Bolts .....                                                                    | 267 |
| 4. Length of Joint Bar .....                                                                                | 268 |
| 5. Lateral Bending .....                                                                                    | 268 |

## CONTENTS—Continued

|                                               | PAGE |
|-----------------------------------------------|------|

*Committee.*

*To the American Railway Engineering Association:*

The Special Committee on Stresses in Track herewith presents its sixth progress report.

## I. INTRODUCTION

1. **Preliminary.**—Since its organization in 1914 this Committee has been cooperating with the Special Committee to Report on Stresses in Railroad Track of the American Society of Civil Engineers, the membership of the two committees being almost identical, and the work has been carried on as one committee. This report is presented simultaneously to the two societies and to the American Railway Association, which has furnished financial support and has otherwise cooperated in the work of the investigation. By this continuing organization, the Joint Committee has been able to outline a constructive program, carry out field and laboratory tests, and interpret results in a co-ordinated way. Five progress reports have been published descriptive of the investigation and its results.

The work herein reported involves two general lines of tests, (1) a continuation of the investigation of the rail-joint reported in the Fifth Progress Report, and (2) a study of the general properties and quality of track as related to the stiffness of the rail support and to the uniformity or variability of the play or vertical movement between rail and tie and between tie and its support on the ballast bed upon the application of load. The investigation of the rail-joint has included laboratory tests of several forms of rail-joints to determine characteristics of their action in resisting the bending moments produced by loads, both through an analytical treatment and by a study of the tests themselves. Study has been given to the action of a joint bar as a girder, to the magnitude of the pressure or load applied on the top fishing surface of the bar by the two rails near their ends and to the position of this load, to the magnitude and position of the supporting reactions at the bottom fishing surface, and to the play between rail and bar (small or large) by reason of lack of fit, and to the corresponding increase in the deflection of the rail-joint. The conditions of the track which affect the development of moment in the rail-joint and the corresponding effectiveness of the joint as a continuation of the rail as a girder have been considered. The angle bar and the symmetrical type of bar have been compared in relation to their usefulness as joint bars. Tests were made on rail-joints in track which have related their behavior in track to the information obtained in the laboratory tests. An important set of tests on rail-joints in track was made with an electric locomotive running at various speeds up to 90 miles per hour. These tests

gave information on the stresses developed at the higher speeds as compared with those found at low speeds. The changes in tension in the joint bolts during the passage of the locomotive wheels were also measured. The effect of various conditions of the joint itself, such as tightness or looseness of bolts, fit or play between rail and joint bar, and condition of tie support, was also investigated.

In the tests of track the effect of various conditions in the track was observed. The differences in the stiffness of the rail support were measured—changes from tie to tie, from one stretch of track to another on the same road, and for different forms of track construction. In particular, the effect of the variability of play between rail and tie and between tie and its bed and the nature and general distribution of the irregularities were investigated and discussed as bearing on variability in the stresses in the rail and in the distribution and magnitude and irregularity of the pressures on the ties and on the ballast beneath them. Information is given on the action of stretches of GEO track with reference to uniformity of stresses in rail, extent of play between rail and tie support, and evenness of bearing of rail on tie-plate and tie-plate on tie.

In the general discussion of rail-joints the functions and the actions of the rail-joint are reviewed, the lateral springing action of joint bars is discussed and the matter of the desirable bolt tension and of fit and limit of play of joint bars is considered. In the miscellaneous remarks on the rail-joint discussion is presented on the shape of the section, on the fit between bar and rail, and on the desirable longitudinal form of the bar (involving controlling the position of the load and reaction bearings between rail and bar), and also on the size and spacing of joint bolts and the length of joint bars. The importance of giving special spacing to joint ties less than for other ties is reviewed. The design of joint bars is discussed and comparisons are made of the properties of a number of forms. Study sections for symmetrical joint bars for the new 112-lb. R.E., 131-lb. R.E., and 152-lb. P.S. rails are given.

In the general discussion of the tests of track, the method of determining the value of the modulus of elasticity of rail support  $u$  for use in calculating rail stresses and depressions and pressures is described. The relations of rail sizes and properties, rail-support stiffness, and wheel spacing to rail stress and moment and depression and to tie load are discussed for groups of wheels as having influence on the durability and upkeep of track. The influence which the strength and stiffness of rail and the stiffness and uniformity of the substructure below the rail exerts upon the quality of the track is discussed. The advantages of stiff rail support on matters of permanence of surface and resulting maintenance are noted. The need for better control of tamping operations to overcome the variability in rail support and its accompanying defects is considered. Altogether, it is concluded that the advantages and the usefulness of track that is smooth under its load, both from tie to tie and through longer distances—high-grade track in all respects—have real values worthy of serious consideration.

2. **Acknowledgment.**—As has been the case in recent years, the expenditures in carrying on the work of the investigation have been taken principally from funds provided by the American Railway Association. The Committee expresses its appreciation of this support. Another fund which has continued to be helpful in meeting expenses is the contribution received from companies that manufacture steel rails, which was acknowledged more fully in the Fifth Progress Report.

The cooperation of railroads in furnishing facilities for the test work is always an important contribution. Three railroads gave excellent opportunities for the conduct of test work by providing locomotives and heavily loaded cars, track, train crews, and

other facilities throughout a considerable time. Acknowledgment for the opportunities and facilities in making the tests on the Pennsylvania Railroad is due T. J. Skillman, Chief Engineer, Robert Faries, Assistant Chief Engineer Maintenance, and F. M. Graham, Assistant Engineer Standards. Credit is due the Westinghouse Electric and Manufacturing Company, F. E. Wynne, Manager Railway Equipment Engineering Department, Charles Jablow, Railway Equipment Engineer, and Messrs. Shamberger and Langer for opportunities to use the testing equipment at Claymont, Delaware, and for the development of a magnetic strain gage suitable for testing rail-joints. Acknowledgment is made to the Chesapeake and Ohio Railway, C. W. Johns, Chief Engineer, for the test facilities accorded at Ashland, Kentucky, and to M. I. Dunn, Jr., Division Engineer, for local arrangements. Credit is likewise due the Missouri Pacific Railroad, the late E. A. Hadley, Chief Engineer, W. J. Burton, Assistant to Chief Engineer, and A. A. Miller, Engineer Maintenance of Way, for opportunity and facilities for making tests of track. Important assistance was also rendered by many operating officials.

The staff engaged in the field, laboratory and office work has continued to give valuable service. E. E. Cress, Assistant Engineer of Tests in charge of conduct of field and office work and the reduction of data and preparation of material, is entitled to special credit; as heretofore, his thorough familiarity with details, keen grasp of the problem, and helpfulness in the study and preparation of the data and report have made his services particularly valuable. Randon Ferguson also has continued to give important and valuable service in the field and laboratory work, the reduction of data, and the preparation of the report. Other members of the staff have given loyal and useful service in the various parts of the investigation.

The University of Illinois has continued to cooperate in the work by giving the use of laboratory, shop, and office facilities, and through the service of members of the staff of the Engineering Experiment Station from time to time.

**3. Previous Progress Reports.**—The principal results of the earlier investigations and their interpretation and findings have been reported in five Progress Reports, which are to be found in the Proceedings of the American Railway Engineering Association as follows: First Progress Report, Vol. 19 (1918) page 873; Second Progress Report, Vol. 21 (1920) page 645; Third Progress Report, Vol. 24 (1923) page 295; Fourth Progress Report, Vol. 26 (1925) page 1081; and Fifth Progress Report, Vol. 31 (1930) page 65. The First, Second, Third and Fourth Progress Reports were also printed in the Transactions of the American Society of Civil Engineers in Vol. 82 (1918), 83 (1920), 86 (1923) and 88 (1925), respectively. Discussion of the investigation by the chairman under the titles "Some Features of Rail Joints" and "The Desirability of Reducing to a Minimum the Present Variability Factors in Track" are to be found in Proceedings of the American Railway Engineering Association, Vol. 33 (1932) pages 746 and 750.

A summarized statement of the scope of the work and the topics and tests included in each of the first four progress reports is given on page 71 of the Fifth Progress Report. This outline of content covering four pages is sufficiently detailed to enable a reader to learn what parts of the investigation are treated in each report and to find the nature and purpose of the tests. Having found in this way a general topic or topics of interest and the number of the volume in which the report is printed, the location of the material can be learned by looking through the Contents at the beginning of each progress report.

The Fifth Progress Report contains chapters on General Structural Action of the Rail-Joint, The Mechanics of the Rail-Joint, The Laboratory Tests, The Field Tests, and General Discussion. The last-named chapter includes such topics as the function of the rail-joint, bolt tension, lateral bending, the rail-joint in track, the design of joint bars, miscellaneous features of rail-joints, uniformity and variability in track, and finally a review which summarizes briefly the topics and findings of the report.

## II. LABORATORY TESTS OF RAIL-JOINTS

4. **The Function and Action of the Rail-Joint.**—In the Fifth Progress Report considerable space is devoted to the functions and action of the rail-joint, both analytically and experimentally. An effort was made to show its physical method of action when load is applied to the rail and rail-joint to learn the mechanics of its structural action; to find where forces act and react between head of rail and upper fishing surface of joint bar and between the lower fishing surface of the joint bar and the base of rail along the length of the rail-joint; to study the elements entering into the flexibility and stiffness and deflection of the rail-joint as a whole and the consequent variations in the pressures or loads on the ties; to learn the effect of high and low bolt tension; to observe the stresses and moments developed in the joint bars and to find wherein the moments developed in track differ from those in the full rail under varieties of conditions; to study the effect of form of section and of fit between rail and joint bars, as well as of lack of fit (play), on distribution of stresses, deflection of the joint, and flexibility of the track; and, among other things, to outline principles and methods that may be useful in designing rail-joints and in giving better understanding of the way in which a rail-joint performs its functions in the track.

Any attempt to summarize the findings of the tests and discussions of the Fifth Progress Report relating to the rail-joint would involve considerable space. The reader who wishes to learn something of the work done is referred to the Review at the end of the Fifth Progress Report and to the articles on the analysis and tests and discussions named in the Table of Contents of the Report. It may be well, however, to refer here to some of the elements in the action of the rail-joint brought out in the Fifth Progress Report. The rail-joint acts principally as a beam or girder. On the application of load to the rail at one or more points producing positive moment in the joint (downward bending), vertical pressures are applied by the head of the rail on the top of the fishing surface of the joint bars near the ends of the two rails, as may be represented at  $Q$  in (a) and (b) in Fig. 1, and at the same time reaction forces act between the base of rail and the lower fishing surface of the joint bars at points farther away from the rail ends, as at  $R$  in (a) or at  $R'$  and  $R''$  in (b). With the more usual forms of rail-joints the position and distribution of these load forces on the top of the bar and of the reaction forces on the bottom are dependent upon conditions such as fit between bars and rail and tightness of bolts. Generally the resultant of the load pressure of rail on top of bar ( $Q$ ) may be considered to be near the rail end as shown in (a) and (b). The resultant of the pressure reactions on the bottom of the bar may sometimes be represented by a single force for each half of the length of bar, as  $R$  in (a), or more commonly, especially for tight bolts and well-fitting joints of such forms, the reaction forces may be approximated by two resultants in each half of the length of the bar as shown by  $R'$  and  $R''$  in (b). For negative bending moments (upward bending) the load pressures will be applied on the bottom of the bar and the reaction forces on the top as shown in (c).

Fig. 1.—DIAGRAM SHOWING VERTICAL LOAD PRESSURES AND REACTIONS ON JOINT BARS. (a) SINGLE REACTION BEARINGS FOR POSITIVE MOMENT. (b) DOUBLE REACTION BEARINGS FOR POSITIVE MOMENT. (c) SINGLE REACTION BEARINGS FOR NEGATIVE MOMENT.

It was shown in the investigation that the shape of section affects the action of the rail-joint. In a shape that is unsymmetrical with respect to the horizontal axis, such as the usual form of angle bar, the mechanics of the beam action differs from that which has been assumed ordinarily in calculations made on rail-joints—the neutral axis under a vertical loading deflects away from the horizontal line, the stresses are not proportional to the vertical distances from the fibers to the horizontal gravity axis, but the stress varies proportionally to the perpendicular distance from the inclined neutral axis developed by the unsymmetrical section and the deflection of the bars is perpendicular to this neutral axis. The amount of these variations depend upon the shape of the bar, the fit between rail and bar, and the restraint produced by fit and bolt tension. The advantages of symmetrical sections and the methods of determining effects of dissymmetry were discussed in the Report including formulas and methods for determining the properties and characteristics of any section.

Fit of the rail-joint and play between rail and bar at ends and middle, even what may be thought to be minute play, were considered in their effect on deflection and depression at the rail-joint relative to that in full rail elsewhere and in their relation to the moments developed in the rail and rail-joint as well as to track maintenance. Attention was given to the usefulness of spacing three or four ties at the rail-joint closer than the tie spacing elsewhere, in reducing the depression at the rail-joint and the moment developed in the joint bars as compared with what they would be for uniform spacing, and thus in improving track conditions and reducing cost of maintenance. Many other matters were discussed and reported in the investigation.

In the chapter on "The Mechanics of the Rail-Joint" of the Fifth Progress Report the flexural action of the joint bar was considered analytically at some length under the assumption that the measured strains in a given section of the joint bar are representative of flexural stresses and that strains caused by bearing pressures or other distortions of the section need not be considered.

In the calculation of moments developed in joint bars from the observed stresses given in this report for both laboratory and field tests, the analytical methods of the Fifth Progress Report are employed as a basis with modifications made to take into account the effect of bearing strains or other local bending when found necessary. In general, the calculated bending moments (or more properly, resisting moments) were computed by equation (67)\*, page 111 of the Fifth Progress Report, using the observed stresses and the coordinates for the two gage lines considered. The two gage lines should preferably be taken at two points as far apart in the section as practicable, one near the top and one near the bottom, and if possible the position of the gage lines should be

chosen where the measured strain is representative of the flexural stress and not influenced by bearing strains or local bending stresses that are found at certain places at certain sections along the joint bar. When a gage line must be placed where it does not give the true flexural stress, as at a point on the upper portion of the inner joint bar where the instrument will be clear of the wheel flange, special approximate methods will have to be used in the calculations to take account of the variation of the strain from that of the flexural stress. These methods of calculation will be described later.

\* Equation (67) is

$$M_x = \left( \frac{I_x x_2 - J_{xy} y_2}{y_1 x_2 - x_1 y_2} \right) s_1 + \left( \frac{J_{xy} y_1 - I_x x_1}{y_1 x_2 - x_1 y_2} \right) s_2 \quad \dots \dots \dots (67)$$

where  $M_x$  is the vertical moment (resisting moment in the vertical planes),  $x_1$  and  $y_1$  are the abscissa and the ordinate of the point in the section for gage line 1 taken with reference to the horizontal and vertical geometrical axes of the section, and  $x_2$  and  $y_2$  are similarly the coordinates for gage line 2, and  $s_1$  and  $s_2$  are the corresponding measured stresses, respectively, at the two gage lines.

TABLE 2

## Description and Properties of Joint Bars

Units are inches and pounds. All values are for a single bar. The subscript denotes the axis to which the properties correspond.

5. Properties of Rails and Joint Bars.—For convenience of reference the geometrical and analytical properties of the sections of rails and of most of the joint bars used in the tests herein reported are given. Table 1 contains the areas, moments of inertia with respect to horizontal and vertical axes, and section moduli of various rail sections with reference to the remotest fiber of the base and the head of rail. Fig. 2 gives sections and dimensions of rails used in the tests. In Fig. 3 are shown sections of joint bars and the position and designation of the gage lines used. In Table 2 are given various properties of the joint bars, including moments of inertia with respect to hori-

Fig. 2.—SECTIONS OF RAILS USED IN THE TESTS.

zontal and vertical axes ( $I_x$  and  $I_y$ ), product of inertia with respect to horizontal and vertical axes ( $J_{xy}$ ) and section modulus with respect to the horizontal axis and the uppermost fiber (the lowermost fiber in the Santa Fe symmetrical bar and study section H)—including several study sections of joint bars which are referred to in Chapter VII.

6. **The Laboratory Tests of Rail-Joints.**—The laboratory tests reported in this Sixth Progress Report relate mainly to the rail-joint. General studies were made of the action of several forms of rail-joint not previously reported on or having features somewhat different from those used in the earlier laboratory tests. Tests with the load and span placed successively farther and farther along the rail and rail-joint to simulate to some degree the condition in track found with a wheel load advancing along the rail and over a rail-joint have given new information on the progressive changes in stresses, moments, and vertical and lateral movements in the rail-joint. The lateral movement of the joint bars in tightening and loosening bolts and the spring (elastic and otherwise) put into the bars by bolt tension have been given some attention. Tests to determine

the relation between stresses at different points over the section of the bar for particular sets of rail-joints were made for use in interpreting the stresses and determining the moments developed in rail-joint and joint bars in the track tested with loaded cars and locomotives. A few miscellaneous tests are also reported.

Following is a description of the procedure in the laboratory tests of rail-joints: Two set-ups were used in the laboratory tests herein reported. For the earlier tests, two equal loads were applied to the rail at points 3 to 6 in. outside of the ends of the joint bars and the supports were placed 16 in. further out from the loads; this set-up developed a uniform bending moment at all sections between the two loads and thus eliminated some possible complications in the action of the rail-joint. For the later tests a single load at the middle of a 48-in. span was applied. This procedure gave a uniformly decreasing moment from load point to ends of span; in some ways it approached more

Fig. 3.—SECTIONS OF JOINT BARS AND THE POSITION AND DESIGNATION OF THE GAGE LINES USED.

closely the distribution of moments at the sections away from the wheel load found in track, though of course the effect of inequalities in tie reactions from point to point along the track was not reproduced.

The measurement of strains in the rail and joint was made by means of 2-in. and 4-in. Berry strain gages. A description of the strain gage is given in the First Progress Report of the Committee on Stresses in Railroad Track (Proceedings of the American Railway Engineering Association, Vol. 19, 1918, page 898). The methods used in taking strain gage readings are also described in the First Progress Report. The 2-in. strain gage was used more especially to obtain the stress throughout the middle portion of the length of the bar where the rate of change of stress was very great. Duplicate readings were always taken. If the two readings did not agree closely further observations were made. It is believed that with the skill used by the observer the errors of observation were less than 600 lb. per sq. in. for the 2-in. gage lengths and 300 lb. per sq. in. for the 4-in. gage lengths. It should be borne in mind that the strains measured are average strains over the gage lengths used. Standard reference bars with the same length of gage line were used throughout the tests and suitable corrections were applied to the readings to compensate for temperature changes and to warn against instrumental mishaps. For special purposes measurements were also made with a  $\frac{1}{2}$ -in. Huggenberger gage attached to the joint bar or rail and measuring  $\frac{1}{2}$ -in. gage length.

Fig. 4.—IMPROVED FORM OF CALIPER EXTENSOMETER.

Two methods were used in measuring the tension in the joint bolts—(a) the caliper extensometer and (b) the extensometer bolts. The earlier form of the caliper extensometer is described in the Fifth Progress Report on page 114. The improved form is shown in Fig. 4. It has a greater range of movement to provide for variations in lengths of bolts. The frame and points were made of Invar steel. The design and material used in the instrument were found to be compensating for temperature changes. The moving point of contact in the new instrument is at the end of a plunger which slides horizontally and the other end of the plunger bears against the lower part of the multiplying lever; thus the position of the point on the end of the bolt is maintained accurately throughout the range of travel. A hole similar to that used for strain gage measurement is drilled in each end of the bolts to receive the conical bearing points of

the instrument. Satisfactory results were obtained without grinding the ends of the bolts. In general, the measurements of tension taken with the new instrument are believed to be accurate within 300 lb., unless the measurement is complicated by temperature changes in the bolt. The bolt extensometers are described on page 114 of the Fifth Progress Report. They are 1-in. heat-treated alloy steel. Fig. 5 gives a view of the extensometer bolts applied to a rail-joint.

Deflection of the rail-joint in the span length was measured with the aid of a dial gage. This gage was mounted on a wooden bar which was supported by conically pointed rods that were fixed rigidly to the bar. When taking readings the points were held in punch marks on the head of the rail. This measurement was thus unaffected by the deflections of the supports upon which the rail-joint rested. The joint bar deflections were measured in the same manner with a bar of correspondingly shorter length. With proper precautions the deflections were obtained within .001 in.

Fig. 5.—EXTENSOMETER BOLTS APPLIED TO A RAIL-JOINT.

7. **General Studies of the Action of Rail-Joints.**—The results of the laboratory tests relating to the general studies of the action of rail-joints will be presented for the several forms of joint bars under separate headings.

7a. **N.Y.C. Rail-Joint for 127-lb. N.Y.C. Rail.**—Both the angle bars and the two pieces of rail in this New York Central rail-joint for 127-lb. rail were new and unused. The section of the bar and the location of the gage lines are shown in Fig. 3 and its properties are given in Table 2. The results given are for a single load of 33,300 lb. at the middle of a span of 48 in. and a maximum moment of 400,000 in.-lb. In Fig. 6 are given the compressive stresses along the top of the bar (point 1) and the tensile stresses along the edge of the lower flange (point 8), one test with an average tension of 20,000 lb. in each of the six bolts and another test with 2,000 lb. bolt tension. It will be noted that at mid-section the stress in the top gage line is more than double that at the gage line near the bottom of the bar and that the tensile stresses at the bottom remain nearly constant throughout the middle 8 in. of length of the bar, while the compressive stress at the top decreases rapidly from the mid-section each way. These differences may be explained by the changes in restraint of the bar from point to point along the length and the consequent modification of the inclination of the neutral axis. For the 20,000 lb. bolt tension the angle of inclination of the neutral axis, as determined by calculation by equation (55) of the Fifth Progress Report and the use of stresses at gage line 1 and 8, changes from  $+15^{\circ}$  at mid-section to  $-15^{\circ}$  at 4 in. on either side. For the 2,000 lb.

bolt tension the angle of inclination is found to change from  $+20^\circ$  at mid-section to  $-3^\circ$  at 4 in. either side. With 20,000 lb. bolt tension the peak in the compressive stress at mid-section is marked; with 2,000 lb. bolt tension the compressive stress falls off less rapidly away from the mid-section. The relative values of the two reaction forces which would give approximately the same moments as are developed along the bars are quite different in the two cases; for 20,000 lb. bolt tension the values are approximately 27,000 and 16,000 lb. for  $R'$  and  $R''$  (see Fig. 1), and for 2,000 lb. bolt tension the interior reactions are smaller than the end reactions, say 14,000 and 17,000 lb., respectively.

The lateral movement of the top and bottom of the angle bar on the application of a load of 25,000 lb. was measured at eight points along the length of each bar with results as plotted in Fig. 7. With a bolt tension of 2,000 lb., at mid-section the movement was .001 in. outward from the rail at the top of the bar and .005 in. inward at the bottom. At the ends of the bars the top movement was .0015 in. outward and the bottom movement .003 in. outward. At intermediate points, the top movement showed changing curvature laterally along the length of the bar, outwardly at the middle and inwardly at the quarter points, while the bottom movement curved inwardly with some regularity from mid-section to end of bar. The results indicate the twisting action of the angle bar from point to point along its length. The marked inward movement of the bottom of the bar at mid-section is attributed to the lack of symmetry of the section of the bar and the consequent inclination of the neutral axis at this section, so that the deflection is downward and inward. For the 20,000 lb. bolt tension the added restraint due to the higher bolt tension has resulted in a reduction in the inward movement of the bottom of the bar at mid-section to about .001 in., while the movement of the top of the bar was not greatly different from that with the lower bolt tension. Elsewhere the movement at both top and bottom was almost entirely eliminated.

Measurements were made at nine gage lines on the mid-section. The distribution of the stresses over the section from top to bottom was found to be quite similar to the distribution observed in the tests of N.Y.C. rail-joints made for the Fifth Progress Report.

It should be noted that this rail-joint has an excellent fit. This was shown not only by inspection and measurements of the rail-joint—the excellence of the fit is borne out by the small magnitude of the vertical movement of the bars with respect to the rail upon application of load and by the form of the curve of stresses and loads along the length of the joint bars.

**7b. Penn. Rail-Joint for 130-lb. P.S. Rail.**—Penn. L-3 rail-joint No. 1 was a new (unused) joint with  $38\frac{1}{2}$ -in. angle bars for 130-lb. P.S. rail. The section of the bar and the location of the gage lines are shown in Fig. 3 and its properties are given in Table 2. In Fig. 8 are given the stresses along the top of the bar and along the edge of the lower flange, one test with a bolt tension of 20,000 lb. and one with 2,000 lb. In this rail-joint, as in the N.Y.C. rail-joint, the stress in the top gage line at mid-section is more than double that at the bottom of the bar and the tensile stress at the bottom remains nearly constant through the middle 8 in. of length of the bar, while the compressive stress at the top decreases very rapidly from the mid-section each way. These differences are, of course, due to dissymmetry in the section of the angle bar and to the restraints applied to the bar. For the 20,000-lb. bolt tension the angle of inclination changes from  $+25^\circ$  at mid-section to  $-45^\circ$  at 4 in. on either side. For the 2,000-lb. bolt tension the angle of inclination changes from  $+25^\circ$  at mid-section to 0 at 4 in. each side. With 20,000 lb. bolt tension the peakedness in the compressive stress at mid-

Fig. 6.—OBSERVED STRESSES IN ANGLE BARS AT SECTIONS ALONG THEIR LENGTH—N.Y.C. RAIL-JOINT FOR 127-LB. N.Y.C. RAIL—BOLT TENSIONS 20,000 AND 2,000 LB.—LOAD 33,300 LB.

Fig. 7.—LATERAL MOVEMENT AT TOP AND BOTTOM OF ANGLE BAR ON APPLICATION OF LOAD OF 25,000 LB.—N.Y.C. RAIL-JOINT FOR 127-LB. N.Y.C. RAIL—BOLT TENSIONS 20,000 AND 2,000 LB.

length is marked. Calculated values of the stresses and moments at different points along the length of the bar which will approximate the measured values may be obtained for the 20,000-lb. bolt tension by considering reactions of 59,000 lb. to be located at 4 in. each way from the rail ends and other reactions of 11,000 lb. at 18 in. each way from the rail ends, while with the 2,000-lb. bolt tension values of reactions at the same two positions given of 30,000 and 18,000 lb. respectively, would approximate the distribution of stress and moment along the length of the bars.

Fig. 8.—OBSERVED STRESSES IN ANGLE BARS AT SECTIONS ALONG THEIR LENGTH—PENN. RAIL-JOINT FOR 130-LB. P.S. RAIL—BOLT TENSIONS 20,000 AND 2,000 LB.—LOAD 33,300 LB.

The lateral movement of the angle bars with respect to the rail on the application of the load of 33,300 lb. at the middle of the 48-in. span was similar to that given in Fig. 7. With a bolt tension of 20,000 lb., the lateral movement of the top of the angle bar at 6, 12, and 18 in. from the mid-section was extremely slight, say about .0002 in., generally outward from the rail, while the bottom points move very slightly one way or the other. At the rail ends, the top of the bar showed a very small outward movement and the bottom moved inward about .002 in. The vertical movement between rail and bar was also very small at the 6, 12, and 18 in. points. At the rail ends the rail and bar moved vertically toward each other about .002 in.; at least part of this movement was a detrusion of the two bearing surfaces, the measurements being made

from a point on the side of the head of the rail about an inch below its top to a point on the web of the bar. With the 2,000-lb. bolt tension, the few lateral measurements made indicated that the bottom of the bar moved inward .003 in. at the mid-section and outward .002 in. at the ends of the bar.

Measurements of stresses were made at 15 gage lines on the mid-section. There was a greater deviation from straight line distribution of stress than with the N.Y.C. rail-joint. It seems probable that this variation was due to differences in the location and amount and concentration of the top bearing pressures in the two joints.

It should be noted that this rail-joint also has an excellent fit. The very small vertical and lateral movements and the form of the stress distribution curve along the length of the joint bars all indicate closeness of fit and restraint of bars.

In Fig. 9 is shown the inclination of the neutral axis at various points along the length of the bar as calculated from stresses measured at the top and bottom of the bar and given in Fig. 8 for tests with 20,000 and 2,000-lb. bolt tension. The change from positive to negative inclination is due to changes in the lateral and vertical restraints at different places along the length of the bar. It is evident that the high bolt tension gives much higher restraints with stronger twisting forces near the middle, and that with low bolt tension there is greater opportunity for lateral movement and lateral flexure of the bar.

Fig. 9.—INCLINATION OF NEUTRAL AXIS IN ANGLE BARS AT SECTIONS ALONG THEIR LENGTH—PENN. RAIL-JOINT FOR 130-LB. P.S. RAIL—BOLT TENSIONS 20,000 AND 2,000 LB.

The changes in bolt tension upon application and removal of load were similar to those for angle bar rail-joints reported in the Fifth Progress Report. On repeated application of load, with 20,000-lb. bolt tension, the tension in the inner bolts dropped off much more rapidly than did that in the intermediate bolts, while at the same time the tension in the end bolts dropped slightly at the first applications and afterward slowly or not at all. For 2,000-lb. bolt tension the tension in the end bolts increased 500 lb. to 1,000 lb. upon applications of load and dropped back upon their removal, the change in tension in the unloaded condition remaining small. The inner and intermediate bolts were little affected by loading and unloading.

The angle bars in Penn. rail-joints 5 and 11 had been taken from the track tested at Claymont, Delaware (tests designated as (f) and (j) in Chapter III "Tests of Rail-

Joints on the Pennsylvania Railroad"); they were the same form of joint bars as Penn. rail-joint No. 1 described above. No. 11 had been in track under heavy passenger traffic for two years, and No. 5 for a few months. In Fig. 10 are given the stresses and moments in Penn. rail-joint No. 11 along a length of 6 in. each way from the mid-section for a load of 33,300 lb. The moments were calculated by equation (67) and the method outlined in Article 4 "The Function and Action of the Rail-Joint." The stresses at mid-section correspond closely with those in Fig. 8. The distribution of stresses along the bar is somewhat different, a condition probably due to wear of the bar. Penn. rail-joint No. 5 gave similar results.

Fig. 10.—OBSERVED STRESSES AND MOMENTS IN  $38\frac{1}{2}$ -IN. ANGLE BARS AT NINE SECTIONS ALONG THEIR LENGTH—PENN. RAIL-JOINT NO. 11 FOR 130-LB. P.S. RAIL—BOLT TENSION 20,000 LB.—LOAD 33,300 LB.

Penn. rail-joint No. 1 (lat. def.), with laterally deformed bars, (also taken from the track at Claymont, Delaware, test designation (g)) had been in service a short time. The regular L-3  $38\frac{1}{2}$ -in. angle bars had been deformed laterally by pressing the head and base laterally outward in an attempt to relieve the bearings between rail and bar on the fishing surfaces at the top and bottom for 3 or 4 in. along the length of the joint at the quarter points. This modification would tend to improve the fit or assure a good bearing at the rail ends and cause the reaction bearings of the loaded joint to be moved along the bottom of the bars to places farther from the middle than is ordinarily found in well fitting rail-joints. The actual condition found in the laboratory test of this joint was that the lateral deformation obtained at the bottom bearing surface was insufficient to assure clearance over the deformed length, and this part of the bar may

have had partial bearing on the base of the rail in this area. Fig. 11 gives the distribution of the stresses and moments along the length of these laterally deformed bars. An effect of laterally deforming these bars seems to be a flattening of the peak of the compressive stress at the middle of the length of the bar and a similar change in the moment diagram. It is evident that the resultants of the top bearing forces are farther from the

Fig. 11.—OBSERVED STRESSES AND MOMENTS IN ANGLE BARS AT SECTIONS ALONG THEIR LENGTH—PENN. RAIL-JOINT No. 1 (LATERALLY DEFORMED) FOR 130-LB. P.S. RAIL—BOLT TENSION 20,000 LB.—LOAD 33,300 LB.

rail ends than is the case with the ordinary bar. It is evident from the shape of the moment diagram in Fig. 11 (flat top and freedom from sharp peak, with a sharply descending line at the ends of the flat top) that the interior reactions ( $R'$  of Fig. 1) may be considered to be located at about 2 in. each way from mid-length, which is greater than the distance usually found in the tests, and that the flatness of the top indicates that the rail ends do not "dig" into the top of the bar as is generally possible. Just what change the deforming process has given to the bar at its middle to produce

the last mentioned effect is not definitely known. The form of the flexure of the bar at the middle of its length effected by tightening both the inner and the intermediate bolts is probably the source of this advantageous condition. It is seen that the tensile stresses along the bottom remain nearly constant through the middle 12 in. of length; this again is due to a change in position in the top bearing forces and probably also to the conditions of restraint. Conclusions on the effects to be obtained by deforming joint bars laterally cannot well be drawn from the test of one rail-joint of the type.

**7c. Penn. Symmetrical Type Rail-Joint for 130-lb. P.S. Rail.**—A pair of the Penn. Symmetrical type of joint bars for 130-lb. P.S. rail, taken from joint 2 in the track of the Pennsylvania Railroad at Claymont, Delaware was tested in the laboratory. The section (see Fig. 3 and Table 2) has an area of 6.37 sq. in., a moment of inertia of 10.25 and a section modulus of 4.60, and a product of inertia of  $-.35$ , as compared with 6.34, 16.55, 6.54, and 6.15 for the corresponding properties of the Penn. L-3 angle bar. It will be noted that the moment of inertia and the section modulus are small as compared with those of the L-3 bar for a horizontal neutral axis and that the design of the section does not give high effectiveness in stiffness and strength.

In Fig. 12 the stresses at top and bottom gage lines under a load of 33,300 lb. are plotted for the middle 12 in. of length, one test with bolt tension of 20,000 lb. and one with 4,000 lb. The upper gage lines are 2.1 in. above the horizontal geometrical axis of the bar and the lower 1.5 in. below it. In the same figure the moments calculated from the measured stress are given for both the 20,000-lb. and the 4,000-lb. bolt tension. It is seen that the results with the two bolt tensions are strikingly similar. The distribution of stresses and moments along the length of the bar are almost identical. The reactions which give approximations to both moment diagrams are 40,000 lb. at 4 in. from mid-section and 15,000 lb. at 16 in. away. Thus the conditions of fit and restraint of the bars are not particularly affected by the change in bolt tension. The ratio between the stresses at the top and the bottom gage lines at mid-section, as influenced by the concentration of bearing pressures at the top fishing surface and by other actions affecting twist and position of neutral axis, are nearly the same, and this is true also at other sections.

The stress at the top of the bar at mid-section was 43,000 lb. per sq. in., which agrees with the calculated stress. For the L-3 angle bars the measured stress for the corresponding point averaged 36,000 lb. per sq. in. while the calculated value on the basis of a horizontal neutral axis was 30,000 lb. per sq. in. The section modulus of this symmetrical type of bar is only 71 per cent of that of the L-3 angle bar and is much smaller than that of study section A of the Fifth Progress Report. The design of this Penn. symmetrical type joint bar is stocky and has a very thick web as compared with the head and base and as compared with other bars. Necessarily it has a restriction in height because of the relatively small fishing height in the 130-lb. P.S. rail section. Relatively few bars of this section have been used in track.

**7d. Santa Fe Symmetrical Type Rail-Joint for 130-lb. R.E. Rail.**—The Santa Fe symmetrical type section for 130-lb. R.E. rail (see Fig. 3 and Table 2) resembles closely one of the near-symmetrical study sections (F) designed for analytical discussion in the Fifth Progress Report. The rail-joints tested were received from the Atchison, Topeka and Santa Fe Railway and had bars 26 in. in length and four bolts, but otherwise the joint bars were the same as those in the track tested on the Chesapeake and Ohio Railway, which were 39 in. long and had six bolts.

Fig. 13 gives the stresses in rail and joint bars for bolt tensions of 20,000 and 2,000 lb. in a test with a load of 50,000 lb. applied equally at two points 36 in. apart on a span of 68 in., thus developing a constant moment of 400,000 in.-lb. throughout the length of 36 in. In the same figure are given the moments in rail and two bars and

Fig. 12.—OBSERVED STRESSES AND MOMENTS IN  $38\frac{1}{2}$ -IN. JOINT BARS AT NINE SECTIONS ALONG THEIR LENGTH—PENN. RAIL-JOINT NO. 5 FOR 130-LB. P.S. RAIL—SYMMETRICAL TYPE JOINT BAR—BOLT TENSIONS 20,000 AND 4,000 LB.—LOAD 33,300 LB.

their sums along the length of the rail-joint for tests with the two bolt tensions. The corresponding values of the stresses and the moments are nearly the same for the two bolt tensions, regardless of the differences in restraint given by the bolt tension. It is

Fig. 13.—OBSERVED STRESSES AND MOMENTS IN RAIL AND JOINT BARS AT TWO GAGE LINES FOR ELEVEN SECTIONS ALONG THEIR LENGTH—SANTA FE SYMMETRICAL TYPE JOINT BARS FOR 130-LB. R.E. RAIL—BOLT TENSIONS 20,000 AND 2,000 LB.—LOAD 50,000 LB.

seen also that the stresses at top and bottom gage lines have nearly the same magnitudes at corresponding points along the length of the bars. This lack of variation is attributable to the symmetry of the section and is in marked contrast to the variability found in rail-joints of the angle bar type. Besides, the stresses, except at areas affected by strong concentration of bearing loads, correspond closely to the stresses found by calculation from the applied moment using the ordinary formulas of mechanics. This form of section thus acts efficiently throughout in the manner of beam action generally assumed in treatises on resistance of materials except as certain points in the section may be affected by the bearing pressures applied by the rail. Other tests, with a single load applied at the middle of the span at the rail ends, gave corresponding values and distributions of stress in the joint bars.

Fig. 14.—VERTICAL AND LATERAL MOVEMENTS BETWEEN RAIL AND JOINT BARS ALONG THEIR LENGTH—SANTA FE SYMMETRICAL TYPE JOINT BARS FOR 130-LB. R.E. RAIL—BOLT TENSIONS 20,000 AND 2,000 LB.—LOAD 50,000 LB.

In Fig. 14 are shown the lateral and vertical movements of the joint bars with respect to the rail at five places along the length. Positive quantities mean an increase in a measurement between rail and bar (opening); negative quantities mean a decrease in the measurement (closure). The measurements of the lateral movements were made from one bar to the other and the two halves of the total movement are the values plotted in plan with reference to two straight lines indicating the initial position of the two bars. For a bolt tension of 20,000 lb., with a load of 50,000 lb. (two-point loading, giving a constant moment of 400,000 in.-lb. along the length of 36 in.) the lateral move-

ment of bars was slight, perhaps .001 in. or less outward movement at the top of the bar at mid-section. At other places the movement of the top was 0 or slightly outward; at the bottom of the bar, the movement was slightly inward along the whole length, perhaps .001 in. at mid-section, and less at other places. For a bolt tension of 2,000 lb., at top and bottom the bar remained close to its initial position throughout the middle 12 in. At the ends there was considerable movement outward averaging about .007 in. at the top and .002 in. at the bottom. The ends of the joint bars were thus not held closely by the end bolts and the bending of the rail at points near the end of the bar was instrumental in forcing the top corner outward.

The magnitude of the bolt tensions has a considerable effect upon the vertical movement between the rail and the joint bars. In Fig. 14 for the 20,000-lb. bolt tension and a load of 50,000 lb., the vertical movement is rather small. For the left half of the joint, the rail head and bars become closer together at the mid-section by less than .001 in. and at the end move apart for somewhat more than .001 in. For the right half, the fit was less close and the rail and bars moved closer at the middle by about .003 in. and at the ends moved apart by the same amount. For a bolt tension of 2,000 lb. the vertical movement was considerably greater. For the left half of the joint, the rail head and bars moved together about .003 in. at mid-section and moved apart .007 in. at the ends. For the right half the movement at mid-section was .015 in. closer for the east bar and .006 in. for the west bar and at the end .007 in. apart for the east bar and .011 in. for the west bar. The sum of the vertical movements at the four points (two ends of bar and two ends of rail) was .008 in. with the 20,000-lb. bolt tension and .030 in. with the 2,000-lb. bolt tension. The latter sum is somewhat above the value found in the tests of the best rail-joints in track heretofore made. It is evident that the higher bolt tensions will reduce the amount of vertical play between rail and joint bar and thus improve the quality of the joint action.

With the 20,000 lb. initial bolt tension, the tension in the inner bolts dropped off with both application and removal of loads, in decreasing amounts, losing 7,000 lb. in four applications, and thereafter remained fairly constant with more applications and removals of load. For the end bolts the loss in tension was 4,000 lb. in four applications, and little thereafter. It is evident that the bars were drawn closer to the rail by the bolt tension with each movement of the bar with respect to the rail (both vertically and laterally) and the accompanying flexure and recovery taking place at an application and a removal. With the 2,000-lb. bolt tension, the tension remains fairly constant in the inner bolts from the first application on through the series. The tension in end bolts increases by about 2,500 lb. at each application of load, resuming nearly the initial tension at each removal of load. This increase is in harmony with the outward movement of the end of the bars shown in Fig. 14 for 2,000-lb. bolt tension and may be contrasted with the lack of movement at the rail ends in the same diagram.

The measurements and test results show that this pair of joint bars do not fit the rail well, especially in one half of the length of the joint bars.

**7e. Norfolk and Western Continuous and Head Free Continuous Rail-Joints for 130-lb. P.S. Rail.**—Tests were made on unused Continuous and Head Free Continuous rail-joints received from the Norfolk and Western Railway to find the magnitude and distribution of stresses in joint bars, vertical and lateral movements between rail and bars, changes in bolt tension, and vertical and lateral deflection with unused 24-in. joint bars for 130-lb. P.S. rail. See Fig. 16 for the sections of the two forms of rail-joints

and the position of the gage lines and Table 2 for the properties. To distinguish between the two forms the regular Continuous will be designated as the head-bearing Continuous rail-joint and the other as the head-free Continuous rail-joint.

In Fig. 15 are plotted the stresses along the length of the bars near the top of the bar and at the outer edge of the bottom flange of the bar for bolt tensions of 15,000 and 2,000 lb., the diagrams at the left being for the head-bearing Continuous bars and those at the right for the head-free Continuous bars. The load of 50,000 lb. was applied in equal parts at two points 42 in. apart on a span of 74 in. in the case of the head-bearing

Fig. 15.—OBSERVED STRESSES ALONG THE LENGTH OF HEAD-BEARING AND HEAD-FREE CONTINUOUS BARS—NORFOLK AND WESTERN CONTINUOUS RAIL-JOINTS FOR 130-LB. P.S. RAIL—BOLT TENSIONS 15,000 AND 2,000 LB.—LOAD 50,000 LB.

Continuous rail-joint, and 36 in. apart on a span of 68 in. in the case of the head-free Continuous rail-joint, making an applied moment of 400,000 in.-lb. throughout the middle 42 in. and 36 in., respectively. For the head-bearing bars the compressive stress at mid-section in gage line 1a is 27,000 lb. per sq. in. with bolt tension of 15,000 lb., and 29,000 lb. per sq. in. with bolt tension of 2,000 lb., while at the bottom edge (gage line 9) the stress with both bolt tensions is 18,000 lb. per sq. in. At a section 4 in. away from the mid-section the stress at the top is only about 40 per cent of that at mid-section; the stress then drops slowly to the last gage line 2 in. beyond. For the head-free bars the stress at the gage line near the top of bar at mid-section (gage line 1) is 22,000 lb. per sq. in. with bolt tension of 15,000 lb., and 24,000 lb. per sq. in. with

bolt tension of 2,000 lb., while at the bottom edge (gage line 13) the stress is 21,000 lb. per sq. in. with both bolt tensions. At 4 in. away from mid-section the stress at the top gage line is 12,000 and 13,000 lb. per sq. in., respectively, with the two bolt tensions. The rounded or blunted shape of the compressive stress diagram in the middle 4 in. of the diagrams for the head-free bars, as compared with the more peaked nature of the same portion for the head-bearing bars, is an indication that the bearing of the rail ends on the head-free joint bar extends farther back from the rail end and the bearing load is distributed over a greater length than is the case with the head-bearing bars; probably too there is less bearing at the extreme end of the rails, since the tops of the head-free bars were found to have moved slightly outward from the rail at mid-length.

In Fig. 16 are plotted the stresses in each bar measured at 14 and 17 gage lines at mid-section for bolt tensions of 15,000 and 2,000 lb. for both head-bearing and head-free bars. A straight line represents the analytical stress distribution over the section calculated by the usual assumptions of beam action. For the two bolt tensions of 15,000 lb. and 2,000 lb., the measured stresses at the top of the two head-bearing bars are respectively 41 and 59 per cent greater than the analytical values, and the measured stresses for the head-free bars are 10 and 22 per cent greater than the analytical values. It will be noted that the stress in the head-bearing bars at gage line 1 is considerably greater than that at gage line 1a, the latter being the gage line used in the diagram in Fig. 15. As it is known that longitudinal stresses at and near a bearing area of high concentration of pressure are greater than at points some distance away from the bearing, it seems quite probable that the stresses in the head-free bar are greater as the fillet of the rail is approached and that the inaccessible part of the bar under the rail head has greater stresses than those measured at point 1.

The stresses across the lower face of the reflexed flange at mid-section (on the same horizontal plane) vary markedly and decrease considerably from the outer edge inwardly. In the head-bearing bars the stresses near the inner edge of the reflexed flange for a bolt tension of 15,000 lb. (gage line 13) are 7,000 and 10,000 lb. per sq. in. in the two bars, while the values next the outer edge (gage line 10) are 19,000 and 23,000 lb. per sq. in., as compared with the analytical value of 19,000 lb. per sq. in. for gage lines on the bottom face of the reflexed flange. Similar variations for the head-free bars are 10,000 lb. per sq. in. near the inner edge and 21,000 lb. per sq. in. near the outer edge at corresponding points, with an analytical value of 19,000 lb. per sq. in. on a basis of a horizontal axis.

Attempts to find an axis of plane bending which would result in stresses being proportional to the distance from the axis proved unsuccessful. The variations in stress at gage lines on the surface of the reflexed flange in both forms of joint bars were not in harmony with the stresses at the upper part of the section. The evidence points to a bending of the section within itself—particularly does the reflexed flange appear to bend independently of the rest of the section. It is plain that this part of the section (the reflexed flange) fails to take its share in resisting the applied bending moment for both forms of bar.

In the lower part of Fig. 17 are given the lateral movements at the top and bottom of the bars at five points along the length for both forms of bars upon application of a load of 50,000 lb. and an applied moment of 400,000 in.-lb., measured after enough applications had been made that upon removal of loads the bars came back very nearly to their initial position. Positive values represent increases in distance between rail and

Fig. 16.—OBSERVED STRESSES AT VARIOUS GAGE LINES AT MID-SECTION OF HEAD-BEARING AND HEAD-FREE CONTINUOUS BARS—NORFOLK AND WESTERN CONTINUOUS RAIL-JOINTS FOR 130-LB. P.S. RAIL—BOLT TENSIONS 15,000 AND 2,000 LB.—LOAD 50,000 LB.

Fig. 17.—VERTICAL AND LATERAL MOVEMENT BETWEEN BAR AND RAIL AT FIVE POINTS ALONG THEIR LENGTH—HEAD-BEARING AND HEAD-FREE BARS—NORFOLK AND WESTERN CONTINUOUS RAIL-JOINTS FOR 130-LB. P.S. RAIL—BOLT TENSIONS 15,000 AND 2,000 LB.—LOAD 50,000 LB.

bar and negative values decreases (closure). The measurements in these tests were made from one bar to the other and the two halves of the total movement are the values plotted in plan with reference to two straight lines indicating the initial position of the two bars.

For the head-bearing bars, for both bolt tensions, at mid-section the top of the bar moved only slightly on application of load; the bottom of the bars moved outward, slightly with a bolt tension of 15,000 lb. (.001 in.), and inward .003 in. with a bolt tension of 2,000 lb. At the ends of the bars, with 15,000 lb. bolt tension, the top had very little movement and the bottom moved inward about .005 in.; with 2,000 lb. bolt tension the ends moved outward at the top about .009 in. and at the bottom inward .008 in. With the lower bolt tension there is then a considerable bending of the bars laterally outward at the top of the bars and their ends are bent inward at the bottom, showing a twist in the bars from middle to ends. Even with 15,000 lb. bolt tension the bottom of the bar was bent inward at the ends of the bar.

For the head-free bars, the top remains fairly free from lateral bending throughout its length, though there is a small reversal of flexure at mid-section; for a bolt tension of 15,000 lb. the lateral movement is slightly outward at mid-section, nothing or slightly outward at the quarter points, and .001 to .002 in. outward at the ends; for the tension of 2,000 lb. the lateral movement of the top is all outward, greater at the ends (from .002 to .005 in.) and about .002 in. at the middle; for the medium bolt tension the lateral movements measured are intermediate between those of the high and the low bolt tensions. The bottom of the head-free bars shows a marked curvature outward; for the bolt tension of 15,000 lb. the movement outward is slight at the middle (about .001 in.) and inward at the other points, having a maximum of .006 in. at one end; for the bolt tension of 2,000 lb., the bottom has about the same curvature in its length, but the lateral movement outward at the middle is quite large, say .008 in., while at the ends it is small; again, the action of the medium bolt tension is intermediate between those of the other two bolt tensions. With all bolt tensions there is twisting of the bar from middle to ends. It is seen that with the bolt tension of 15,000 lb. the two forms of Continuous bars have nearly the same lateral movement throughout the length, but that with the bolt tension of 2,000 lb. the amount of the lateral movement differs in the two cases. However, the character of the curvature is similar.

The vertical movement between bar and rail at six points along the bars upon the application of the load of 50,000 lb. is also plotted in Fig. 17 for the two bars of a joint as distances from a straight line representing the initial position for the two forms of Continuous rail-joint. For the head-bearing bars, with a bolt tension of 15,000 lb., at the rail ends the vertical movement is quite small, about .001 in. of closure at the four points; at the end of the bars, the movement is about the same amount but of opposite nature. With a bolt tension of 2,000 lb. considerably more movement occurs. At mid-section, one bar has little or no movement and the other bar shows .002 and .004 in. closure; at the ends of the bars the movement ranges from .006 to .019 in. opening. For the head-free bars, with a bolt tension of 15,000 lb., the vertical movements are markedly greater than those found with the head-bearing bars at the same bolt tension. At mid-section the movement shows a closure of .003 in. and at the ends of the bar an opening ranging from .002 to .008 in. Although these changes may seem small, vertical movements of this magnitude in track tests of other forms of bars have been found to accompany unfavorable conditions in the rail-joints. With a bolt tension of 2,000 lb. the vertical movements of these head-free bars become considerably greater,

but their magnitude is comparable with those found with the head-bearing bars at the same bolt tension. Measurements made with bolt tension of 8,000 lb. gave results intermediate between those with the two bolt tensions reported. It will be seen that the movement with the head-bearing bars and high bolt tension in the joint tested compares favorably with that for other forms of joint bars having similar bolt tensions and that the movement with the head-free bars under the same bolt tension shows considerably greater play.

The changes in bolt tension upon loading and unloading indicate a difference in action in the two forms of Continuous rail-joints. Fig. 18 records the changes in bolt tension with both forms of Continuous bars. With an initial bolt tension of 15,000 lb. the tension in the inner bolts of the head-free joint drops off abruptly on the first application of load in much the same manner as has been found in other rail-joints including the head-bearing Continuous rail-joint. With further applications there are slow decreases in tension in the inner bolts, but little difference between loaded and unloaded condition. The tension in the end bolts, though slowly decreasing, increases from the previous bolt tension in the unloaded condition by 2,000 and 4,000 lb. upon each application of load. An increase in the tension of the end bolts on application of load has frequently been found with other forms of joint bars at similar bolt tensions, but such increases have been small—not more than 500 lb. With initial bolt tension of 2,000 lb. the tension in the inner bolts of the head-free bars increased about 3,000 lb. with each application and that in the end bolts about 7,000 lb. The change in tension in the inner bolts is different in character from the action in other joints tested, including the head-bearing Continuous (see top of Fig. 18), for the change in tension in inner bolts has usually been a small decrease in tension, if any change; and the increase in the tension in the end bolts upon loading is unusual in amount, being several times that ordinarily found. It may be added that for both forms of the continuous joints the bolt tension changes are in harmony with the lateral movements of the bars.

Measurements of deflection under load were taken along three longitudinal lines or elements of the head-free Continuous bars extending over the length of the bar, one line through points at the top of the bar, one near the outer edge of the bottom of the reflexed flange and one near the inner edge of the reflexed flange. The three points through which these three lines pass are near gage line 1, 14 and 17, respectively, indicated on the section of the head-free bar in Fig. 16. For the bolt tension of 15,000 lb., the deflection at the middle of the line along the top of the bar was .017 in., that for the outer bottom line .008 in. and that at the inner bottom line .020 in. For the lower bolt tensions the corresponding deflections were .019, .010 and .022 in. The lack of uniformity in the three deflections is taken as one evidence that the section of the bar does not remain integral in bending.

Measurements with thickness gages showed that the bottom of the rail and the top of the reflexed flange in both forms of Continuous bars were not in contact at any point through the length of the bars, both when loaded and when unloaded.

The preceding discussion of the test results warrants the following comments on the action of the two forms of the Continuous rail-joint.

1. The longitudinal distribution of compressive stress for a set of gage lines a little below the top point of the head-bearing bar along its length is similar to that found with well-fitting bars of other types. The distribution of the corresponding stress with the head-free bar is less peaked (somewhat blunted), indicating a distribution of the top rail-bearing pressure along a greater distance back from the rail ends.

Fig. 18.—CHANGES IN BOLT TENSION WITH REPEATED APPLICATION AND RELEASE OF LOAD —HEAD-BEARING AND HEAD-FREE CONTINUOUS BARS—NORFOLK AND WESTERN CONTINUOUS RAIL-JOINTS FOR 130-LB. P.S. RAIL—BOLT TENSIONS 15,000 AND 2,000 LB.—LOAD 50,000 LB.

2. The measured stress at mid-section on the corresponding gage lines is 5,000 lb. less in the head-free bar than is found in the head-bearing bar. As the contact of the rail-bearing pressure in the head-free bar is well around on the fillet of the rail head and as the neutral axis of bending may be inclined negatively, it is not known where the maximum stress in the bar is located, nor to what extent the stress at the gage lines is decreased by the effect of the bearing pressure applied along the fillet of the rail head, and it is quite probable that a stress exists which is higher than the one measured at gage line 1. The measured stress in both forms of bars is considerably higher than the calculated stress of 20,000 lb. per sq. in. based on a horizontal neutral axis through the center of section. The measured stress at gage line 1a in the head-bearing bar is about 27 to 37 per cent more than the analytical stress and in the head-free bar at gage line 1 about 10 to 25 per cent higher.

3. The measured stress in the lowest fiber of the bars differed from the calculated value based on a horizontal neutral axis through the center of the section—in the case of the head-bearing bars it was about equal near the outer edge of the reflexed flange and about 50 per cent less near its inner edge, and in the case of the head-free bars about 15 per cent greater near the outer edge and about 50 per cent less near the inner edge. This indicates that the greater part of the reflexed flange is only partly effective in resisting bending moment in the manner assumed in ordinary beam analysis and that the bar does not have the full strength given by calculations.

4. The distribution of the measured stresses throughout the mid-section of the joint bars indicates that the reflexed flange does not act integrally with the remainder of the section during flexure.

5. For the head-free bars the stress at the bottom of the reflexed flange at one point near its inner edge (gage line 17 of section) is only less than half of the stress developed at the gage line on the same level near the outer edge of the flange (gage line 14), the relative values being 10,000 lb. per sq. in. and 22,000 lb. per sq. in. respectively.

6. For the head-bearing bar the vertical movement of the bar with respect to the rail was small and compared favorably with well fitting bars of other types. For the head-free bars at the higher bolt tension the vertical movement was greater, with closure in the distance between rail head and bar at the rail ends and separation at the bar ends.

7. For the head-free bars, the lateral outward movement of the bar at the rail ends indicated a change in position of rail-bearing contact upon application of load.

8. For the head-free bars the increase of tension in the inner bolts upon application of load (an action not found in other forms of bars) is in harmony with the observed lateral movement of the top and bottom of the bar at mid-section. Also, the increased tension in the end bolts was much greater than in other forms of bar, which corresponds with the large outward movement of the bars observed at the ends of the bars. High tension in the bolts causes both forms of rail-joints to act more satisfactorily—especially in the head-free bars. It follows that it is very desirable to maintain high bolt tension in the head-free form of rail-joint.

9. The observed stresses and deflections indicate that the section of the bar under bending load does not act fully integrally, and that the reflexed flange bends independently somewhat with respect to the remainder of the section.

10. The two forms of Continuous bars have heavy, sturdy sections, and though the whole area of the section is not fully effective in flexural resistance the stresses are relatively small. The placing of metal under the rail gives an opportunity of increasing

the section of the bar, but with this disposition some loss in effectiveness of the added metal must be accepted. With both forms of Continuous bars, it is essential that the fit between bar and rail be excellent.

7f. **Muller Rail-Joint for 130-lb. R.E. Rail.**—An unused Muller rail-joint for 130-lb. R.E. rail (drop-forged) received from the Baltimore and Ohio Railroad was tested for resistance to positive and negative moment. Fig. 19 illustrates the form of the bar in the rail-joint tested. The joint bars have a top bearing below the head of the rail for a length of 3 or 4 in. each way from the rail ends. On the base of the rails, a bearing extends for a length of about 3 in. from the two ends of the bar. From the drawing of the rail-joint it seems to be intended that there should be also a reaction bearing for a length of 4 or 5 in. each way from the mid-length of the bars and no bottom bearing contact between this and the end-bearing areas, but there was found to be no reaction bearing at the bottom of the bars throughout the length of the bar except in the end portions. The shape of the bar was such that a considerable tension was required in the end bolts to bring the bars to a bearing on the base of the rail at the ends of the bars, and there could be no bearing on the rail head near the bar ends. The inner bolts aid in holding the bar in place throughout its middle portion. The section is not uniform throughout the length of the bar; at the middle it is much heavier than at the ends. From the drawing it is apparently intended that the inner surfaces of the bar conform fairly closely to the rail contour over the whole vertical section of the bar throughout the middle part of the length.

Fig. 19.—MULLER JOINT BAR FOR 130-LB. R.E. RAIL.

The form of the rail-joint was such that under positive moment the bearing pressure of the rail head is applied at the top of the joint bars near the rail ends as in the ordinary forms of joint, and the reactions of the bars on the base of rail are applied entirely at the ends of the bar. The high tension put into end bolts in forcing the ends of the bars into place bent the bars laterally and put high initial bending stresses into the fibers of the bars, especially in the extreme outer fibers of the bottom portion of the section at mid-length, as will be seen from the results of the test. The tightening of the end bolts also lifted the top bearings at the rail ends with respect to the level of the reaction bearings at the ends of the bars—in other words it produces a camber in the rail-joint from points on the rail beyond the end of the joint bars. It will be seen that upon the application of negative moment the reaction at the top of the bar can be applied on the top fishing surface of the bars at areas only between 3 and 4 in. from the ends of the rail and that there must be considerable vertical movement between bar and rail before resistance to negative moment will be available in any way.

In the tests of the Muller rail-joint the loads were applied at the middle of a 48-in. span, the maximum load being 25,000 lb. and maximum bending moment 300,000 in.-lb.

In Fig. 20 the stresses at the mid-section near the top (gage line 1, see Fig. 19) and at the extreme outside edge of the bottom flange (gage line 10) are plotted for loads of 8,300, 16,700 and 25,000 lb. on the first application of positive moment, and for the fifth application of 25,000 lb. The stresses shown are seen to be proportional to the loads. In the first loading the stresses at the top gage line for the load of 25,000 lb. are 27,000 and 40,000 lb. per sq. in. in the two bars (compression) and 2,000 and 10,000 lb. per sq. in. at the bottom gage line (tension). On the fifth application of 25,000 lb. the stresses in the two bars were 30,000 and 42,000 lb. per sq. in. at the top gage line and 1,000 and 8,000 lb. per sq. in. at the bottom gage line. The rail-joint was then turned over and loads of 8,300 and 12,500 lb. were applied, developing negative moments of 100,000 and 150,000 in.-lb. at mid-span. Considerable deflection was developed on the application of load. On the first application of the load of 12,500 lb. the stresses were 17,000 lb. per sq. in. tension at the original top gage line (gage line 1) and 1,000 lb. per sq. in. tension at gage line 10. All the above values were obtained by using the original zero of measurement, although in the application of the several loadings the readings in the unloaded condition indicated variations in the stress condition, due doubtless to changing adjustments of the bar with respect to the rail throughout the length of the rail-joint.

Fig. 20.—OBSERVED STRESSES AT MID-SECTION OF JOINT BARS NEAR TOP OF BAR AND AT EXTREME OUTSIDE EDGE OF BOTTOM FLANGE ON APPLICATION OF LOAD. POSITIVE LOAD OF 25,000 LB. AND NEGATIVE LOAD OF 12,500 LB. EACH REPEATED FIVE TIMES—MULLER RAIL-JOINT FOR 130-LB. RAIL.

A tension of 29,000 and 17,000 lb. had been applied to the two end bolts in assembling the joint. The bolts were loosened at the end of the tests described above and strain gage readings were taken. The results show that initial tensile stresses of 31,000 at the top (gage line 1) and 74,000 lb. per sq. in. at the bottom (gage line 10), due to the initial tightening of the bolts, existed in the bars in the assembled condition of the rail-joint, assuming that the elastic limit is not exceeded. In Fig. 21, these initial stresses have been taken into consideration and the total resultant stresses, based on the original loosened, unstressed condition of the bars with bolts loose, are shown for each gage line

for each application and release of load. The values shown in the figure are then the sum of the stress due to bending the bars in tightening the end bolts and that due to loading the joint. On the application of the load of 25,000 lb. to the assembled joint the actual stress at the top gage line, which had an apparent average compressive stress of 34,000 lb. per sq. in. as shown in Fig. 20, actually has a resultant compressive stress of about 3,000 lb. per sq. in. as shown at the bottom of the figure, and the bottom gage line, which had an apparent tensile stress of 6,000 lb. per sq. in., has an actual tensile stress of 80,000 lb. per sq. in., again assuming that the elastic limit has not been exceeded. It is seen that the initial stresses put into the bar by tightening the end bolts have

Fig. 21.—TOTAL RESULTANT STRESSES AT MID-SECTION NEAR TOP OF BAR AND AT EXTREME OUTSIDE EDGE OF BOTTOM FLANGE, INCLUDING ASSEMBLY STRESSES AND LOAD STRESSES—POSITIVE AND NEGATIVE LOADING—MULLER RAIL-JOINT FOR 130-LB. RAIL.

greatly changed the resultant stresses present under the applied load. Under the application of negative moment the initial stresses at the top of bar are increased by 16,000 lb. per sq. in., and those at the bottom gage lines are increased about 2,000 lb. per sq. in. The stresses given in Fig. 20 and 21 are based on the assumption that the elastic limit of the metal has not been exceeded.

In assembling the rail-joint, on the tightening of the end bolts to the tension of 29,000 and 17,000 lb. per sq. in. the rail ends at the middle of the joint rose from a straight line joining two points 48 in. apart up to a height of .125 in. The deflections at mid-span are given in Fig. 22. The deflection upon application of load of 25,000 lb. was almost the same as the camber put into the 48-in. length by the tightening of the

bolts. This deflection of .125 in. is very much more than that obtained with the same load with the other joints tested and reported in this article.

On application of negative moment the deflection was marked, .2 in. in the center of a span of 48 in. for load of 12,500 lb. and negative moment of 150,000 in.-lb. The play or movement in unloaded conditions between the position on the release of the positive moment of 300,000 in.-lb. and that on the release of the negative moment of 150,000 in.-lb. was .15 in. In other words, the middle of the span of 48 in. would move .15 in. after the release of positive moment before the joint would take negative moment. It is evident that under track conditions the rail-joint is not likely to move upward sufficiently to give negative resistance and thus a negative moment would not ordinarily be developed in the track under usual conditions.

Fig. 22.—DEFLECTION AT MIDDLE OF SPAN OF 48 IN.—MULLER RAIL-JOINT FOR 130-LB. RAIL—POSITIVE LOAD OF 25,000 LB. AND NEGATIVE LOAD OF 12,500 LB. EACH REPEATED FIVE TIMES.

The relative vertical movement between the bars and the rail on application of load was measured. At mid-section the distances to the heads of the rail ends decreased by .003 in. for the load of 25,000 lb. At the ends of the bars the increase ranged from .002 to .009 in. at the places where bearing contact was obtained in the assembly of the joint, the latter movement being much larger than those reported for the other rail-joints. The movement varied somewhat with the load. When the positive moment had been released and the negative load of 12,500 lb. had been applied the first time, the vertical movement between bar and rail amounted to .015 in. at mid-length and .050 in. at the ends. Much of this movement occurred before the joint took moment,

and on release of negative moment the bars failed to return to the first position by .012 in. at the middle and .038 at the ends.

For the middle portion of the length there was no contact between the under side of the bars and the base of rail in either the loaded or unloaded condition, as found by observation with thickness gages, and consequently there was no reaction bearing in this portion of the length of the bars and the reaction forces were limited to the areas near the ends of the bars.

It should be noted that the maximum load applied to this rail-joint was only 75 per cent of the maximum loads applied to the other rail-joints discussed in the laboratory tests, this limitation being made because it was desired not to overstress the bars.

The exceedingly high initial stresses put into the bars through tightening the end bolts to bring the end bearings into working position and a further increase in stress at the lower gage line on applying load, which were found in the rail-joint tested, emphasize the need of exercising control of the form of the bar longitudinally in its design and manufacture in order to limit the stresses developed in the bar by installation and use.

**8. Action of a Rail-Joint under an Advancing Load.**—The laboratory tests on rail-joints have usually been made either with a single load applied at the middle of a simple span or with two loads placed symmetrically with respect to the rail-joint and the beam supports. With a view to learning the changes in the action of the rail-joint as a load advances toward the rail-joint and passes on over it, a series of tests was made on a number of rail-joints by applying a single load at the middle of a 48-in. span and moving the load and supports along the length of the structure by increments of 6 in. for succeeding tests in an effort to simulate to some degree the action of a moving wheel load along the track. Although the method of supporting the rail is quite unlike the reaction support of ties and ballast in track, the form of the moment curve is not unlike that developed in track and the tests approximate closely enough to successive actions of the rail-joint in track to give significant information. One purpose of the tests was to see if evidence could be obtained of any sudden changes in the deflections, movements, or stresses within the rail-joint that would produce undesirable accelerations or impacts as the wheel approaches and passes over a rail-joint. These tests were made in advance of the measurement of stresses in joint bars under rapidly moving loads in the tests on the Pennsylvania Railroad at Claymont, Delaware, and the information gained was also of value in planning these moving load tests in track and in interpreting the results.

The laboratory tests with advancing loads were made on three forms of rail-joint—(1) the New York Central rail-joint for 127-lb. N.Y.C. rail and 38-in. angle bars, (2) the Santa Fe rail-joint with 130-lb. R.E. rail and 26-in. bars of near-symmetrical section, and (3) the Illinois Central rail-joint for 90-lb. A.R.A.-A rail and 24-in. angle bars. The sections of the joint bars are shown in Fig. 3 and also the position of the gage lines, except that of the I.C. joint, which is shown in Fig. 25 of the Fifth Progress Report. The properties of the joint bars are given in Table 2. The first and the last mentioned joints were described in the Fifth Progress Report. The Santa Fe joint bar has the same section as the joint bars used in the tests on the Chesapeake and Ohio Railway at Ashland, Kentucky, though the latter have a length of 39 in. Generally, tests were made on two or more joints of each form and in several instances the tests were repeated or made a second time in a different way. However, the principal tests of each form of joint were made on one joint. Considerable time was given to these tests, as the procedure was time consuming.

The N.Y.C. rail-joint tested showed excellence of fit and little play between joint bar and rail throughout. The test results were very consistent and the uncertainties few. The tests were made after work had been done with the other rail-joints and were carried out in greater detail. For these reasons the tests of N.Y.C. rail-joint will receive the greatest attention.

In the principal test of the N.Y.C. rail-joint made with advancing load, the joint was first inverted and a negative load of 13,300 lb. (40 per cent of the moment applied to the rail-joint in each of the positive loadings) was first applied at mid-length of the joint (designated as *A* in Fig. 23) with the reaction supports placed 24 in. each way. The regular load of 33,300 lb. was then applied positively (downward with respect to the ordinary position of the rail) at a point 24 in. to the left of mid-length of the joint (*B* in Fig. 23) and with the supports 24 in. each way, the right reaction thus being at mid-length of the joint. The next loading was made with the load and supports moved 6 in. to the right (*C*), followed with successive similar loadings 6, 12, and 18 in. farther to the right (*D, E, F*) (the last mentioned being at mid-length of joint) and then others at 6, 12, 18, and 24 in. to the right of mid-length of joint (*G, H, I, J*). The joint was then reversed in vertical position and a negative load of 13,300 lb. again applied at the middle (*K*). The bolt tension in this set of tests was nominally 20,000 lb. Stresses were measured at nineteen 2-in. gage lines along the top of the angle bars (gage line 1) and at the same number along the outer edge of their lower flange (gage line 8).

The moments developed in the various sections of the bars have been calculated from the stresses observed at the top and bottom gage lines by equation (67) given in Article 4 "The Function and Action of the Rail-Joint", which takes into account the inclination of the neutral axis. This equation expresses the relation between the vertical bending moment and the stresses at two gage lines in the section. The values of the moments in the two bars thus obtained are plotted in Fig. 23 for the eleven loadings, and inspection of the diagrams will show that with one reaction support at mid-length of joint (either the right or the left one, *B* or *J*) the greatest moment in the bars was at 8 or 10 in. from mid-length—about 8 per cent of the maximum moment developed at mid-section with the load over it; the moments in the half of the bar in this loading are evidently developed with the bending of the rail itself and no moment is carried by the bars to the other rail. For all other loadings the maximum moment in the bars is at their mid-section. For positions of the load other than the end position and the one at mid-length there is generally a hump directly under the load, more or less pronounced; it is evident that this is occasioned by the greater curvature developed in the rail directly under the load and the corresponding changes in the positions of the vertical forces which apply load to the bars.

In Fig. 24 the moments developed at thirteen sections by the various loads are plotted as influence lines—that is, for each of the thirteen gage lines the moment corresponding to each of the nine positions of the load is given. The position of the load which gives the plotted moments at the several sections along the length of the bar (mid-section, 2 in. left, 2 in. right, etc.) is indicated by the letters *B, C*, etc., which correspond to the positions of load shown in Fig. 23. To conserve space, the values for sections at the left of the mid-length of the joint and at the same distance to the right are plotted together for common positions of the loads. It will be noted that the corresponding gage lines in the two halves of the joint have values of the moments nearly the same in amount for corresponding relative positions of the load. For all those gage lines having the load directly over it this position of load gives the greatest moment for the given section, and this would probably be true for the other gage lines if loads had been placed

immediately over them. The changes in moment are uniformly gradual; there is no evidence that further increases would be caused by impact or obstructed acceleration.

The distribution of the negative moment along the length of the bars (see Fig. 23) shows a rounded instead of a peaked shape at and near mid-section. It is stated elsewhere that the data of lateral movement of the bars under load show a slight outward movement at mid-section, and the load applied by the rail base on the bottom of the bars (negative bearing pressure) evidently extended farther away from the rail ends than was the case in the positive loading and thus the resultant of the bearing pressures was farther from the rail ends. In other respects the distribution of moments along the bars is similar to that with the positive loading.

In this N.Y.C. rail-joint for the same loadings measurements were taken of lateral movement between rail and bars at both top and bottom for points at ends of bars, at the mid-length for each rail end, and at 6 in. and 12 in. each way from mid-length. These measurements for positive loadings show that at the rail ends the bottom of the bar moves inward slightly when the load reaches a point producing a positive moment in the bars at mid-section (load 18 in. from middle of joint), the movement increases as the load advances and the moment increases, and it becomes a maximum when the load is at mid-length; the lateral movement at mid-length then decreases as the load passes over the joint becoming negligible as the moment developed is negligible. The value of the lateral movement at the bottom of the bar along its length ranged from less than .001 in. when first measurable to a maximum of .002 in. This inward movement is partly attributable to the inward pull of the inner bolts while the bottom of the bar is freed from initial contact with the base of rail when moment is developed at mid-section and naturally may be greater with unsymmetrical sections. At the same time the top of the bar at mid-section moved slightly outward a maximum of .0005 in. as measured when the load reached mid-length. At other points the lateral movements were all small except that when the load had advanced past the mid-section the corresponding ends of the bars at both top and bottom moved outward a maximum of about .0015 in.

Vertical movements between rail and bars upon application of load were measured at the same eight points. These movements are all quite small, ranging from 0 to .001 in., and the fit between rail and bars is correspondingly close. In the case of the negative moment (40 per cent of the positive moment) the vertical movements between rail and bar are still smaller—all of them under .0005 in. Fig. 25 shows influence lines for vertical movement between rail and bars at one-half inch each way from mid-section, at sections 12 in. each way from mid-section, and at ends of bars, each for the positions of load indicated at the top of the diagram. The measurements show that as the load advanced along the rail-joint the vertical movement at mid-section (closure) increased, becoming .001 in. with the load over the rail ends, and then decreased with further passage of the load. With the load at the approach end of the bars, a separation between rail and bar began as the load advanced beyond the first bar end, then decreased as the load advanced; a similar opening on the farther end began when the load had advanced to within 6 in. of mid-section, then increased, and finally closed as the load passed beyond the farther bar end. These differences in vertical movement between rail and bar are due to the difference in curvature of rail and bar as the load passes along—when the load is 12 in. left of mid-section the curvature of the rail in that vicinity is a maximum and that of the bar is small so that the bar end necessarily is deflected downward from the rail head, and a similar movement takes place at the far end when the load has advanced to that half of the joint. When the load is near mid-section the curvature of

Fig. 23.—MOMENTS IN TWO BARS AT VARIOUS SECTIONS ON APPLYING AN ADVANCING LOAD ALONG A RAIL-JOINT—N.Y.C. 38-IN. ANGLE BARS FOR 127-LB. RAIL—LOAD OF 33,300 LB. AT MIDDLE OF SPAN OF 48 IN.—ALSO FOR A NEGATIVE LOAD OF 13,300 LB. AT MID-LENGTH OF JOINT.

Fig. 24.—INFLUENCE LINES FOR MOMENTS IN TWO BARS AT VARIOUS SECTIONS FOR AN ADVANCING LOAD ALONG A RAIL-JOINT—N.Y.C. 38-IN. ANGLE BARS FOR 127-LB. RAIL—LOAD OF 33,300 LB. AT MIDDLE OF SPAN OF 48 IN.

the rail near its end is a minimum and that of the bar near mid-section is a maximum so that the rail ends must bear heavily on the top of the bar, in fact this difference in curvature of rail and bar and the differences in their direction are the source of the "digging in" of the rail end at the fishing surface of the bar. While these movements and differences are small, they are very significant in relation to the wear and cutting of the metal and are encountered in much greater degree in the track.

The deflection of the rail and rail-joint in 48 in. with the load of 33,300 lb. at mid-length of joint was .050 in., as compared with .030 in. calculated deflection for full rail. With the load and supports moved 6, 12, and 18 in. either way the measured deflection at mid-span was .042, .034, and .035 in., respectively. Because of the excellence of the fit, the increase in deflection due to the presence of the rail-joint was smaller than has ordinarily been found.

Fig. 25.—INFLUENCE LINES FOR VERTICAL MOVEMENTS BETWEEN RAIL AND BARS AT SIX POINTS ALONG THE LENGTH OF THE RAIL-JOINT ON APPLYING AN ADVANCING LOAD—N.Y.C. 38-IN. ANGLE BARS FOR 127-LB. RAIL—LOAD OF 33,300 LB. AT MIDDLE OF SPAN OF 48 IN.

Using bolt tensions of both 20,000 and 2,000 lb. tests were also made with the N.Y.C. rail-joint by applying a load of 33,300 lb. at the middle of the joint and then moving the load and supports 6, 12, and 18 in. to the left. The measured stresses for the load over the rail ends have already been given in Fig. 6. The moments observed in the bars at mid-section were closely the same for both bolt tensions, as were also the moments in the joint bars at sections under the load for other loadings. The observed moments at sections in the right halves of the bars, especially at a right support, were larger with the bolt tension of 2,000 lb. than those found with bolt tension of 20,000 lb. for loadings other than at the middle of the rail-joint. This surplus of moment in the joint bars was present from even beyond the right support. The lateral movement at mid-section at all loadings with advancing load was considerably greater with the low

bolt tension than with the high bolt tension. The vertical movements between rail and bar were somewhat greater with the low bolt tension, but the difference was not as great as has been found with other rail-joints tested.

For the Santa Fe rail-joint (symmetrical section, length 26 in.) an advancing load of 33,300 lb. was applied at a load point 18 in. to the left of the middle of the rail-joint with a span of 48 in., followed by applications of the load at 12 and 6 in. to the left of the mid-section, at mid-section, and 6, 12, and 18 in. to the right of the mid-section. A negative moment equal to 40 per cent of the positive moment was applied before and after the loadings named. In Fig. 26 are plotted the moments at eleven sections observed under these nine loadings. The same designation is used for indicating the position of the load with respect to the rail ends as was used in Fig. 23. For the load 18 in. left of mid-section (load at *C*) the moment measured at mid-section of bars was 110,000 in.-lb., about the amount of the applied moment at that point in the span. For load at 12 in. left of mid-section naturally no moment was developed in the bars immediately under the load. This is of course in contrast to the moment developed in the N.Y.C. 38-in. bars at a section 12 in. left of mid-section with the load applied above that section; the moment developed in the bars at this section was 80,000 in.-lb., which is 40 per cent of the moment developed at mid-section with the same loading and a third more than the moment at this section with load at mid-length, a condition that is caused by the accompanying bending of the rail itself immediately above this section. A similar comparison holds with a load 12 in. to the right of mid-section. It is seen that with an advancing load the longer bars take moment in the first third of the half length of the bar (even greater than is developed at these sections remote from mid-section as the load moves along to mid-section and beyond), whereas in the shorter bars it is not possible, of course, to develop moment at a section at the ends of the bar. The shorter bar shows the same tendency to increased moment under the load as the load moves along that was found in the longer bar of the N.Y.C. rail-joint, although the hump is less pronounced and may be somewhat masked by differences in fit. The influence lines for moments in the Santa Fe rail-joint (not plotted) are quite similar to those given for the N.Y.C. rail-joint, but the difference in fit at the two halves of the Santa Fe joint bars renders the influence lines for corresponding sections in the two halves of the length less consistent than shown in the Fig. 24. The vertical and lateral movements between rail and bars are likewise similar to those of the N.Y.C. rail-joint, though naturally on the looser half of their length the movements measured are somewhat larger.

Tests were made with I.C. rail-joint No. 3 (other tests with this rail-joint were reported in Fig. 35-39, 46-50 and 56-57 of the Fifth Progress Report) by applying loads at mid-section and at 6, 12, and 18 in. left of mid-section, bolt tensions of 20,000 and 2,000 lb. being used. This rail-joint was a used joint, somewhat worn, and only one of the rail ends was the original rail. The fit between rail and bar for the right half of the joint was poorer than that for the other half, and the difference showed up in differences in stresses and in vertical movements in the two halves of the bars. In moment distribution diagrams of these tests (not given), the moments in the left half of the bars drop off quickly from the value at the mid-section, as is usual with well fitting bars, whereas those on the right half sloped gradually to nothing near the right end, showing that the reactions of the right half were nearer to the ends of the bars than usual. At the section 6 in. left of mid-section in tests with bolt tension of 20,000 lb. there was a noticeable hump in the moment distribution diagram, as was found in the N.Y.C. and Santa Fe rail-joints tested with advancing loads. This hump was not present in tests with a bolt tension of 2,000 lb., the looseness evidently giving a chance for adjustment

Fig. 26.—MOMENTS IN TWO BARS AT VARIOUS SECTIONS ON APPLYING AN ADVANCING LOAD ALONG A RAIL-JOINT—SANTA FE SYMMETRICAL TYPE 26-IN. JOINT BARS FOR 130-LB. R.E. RAIL—LOAD OF 33,300 LB. AT MIDDLE OF SPAN OF 48 IN.—ALSO FOR A NEGATIVE LOAD OF 13,300 LB. AT MID-LENGTH OF JOINT.

between the curve of the rail and that of the bar, otherwise the moment distributions for the two bolt tensions show similar results. The vertical movement between rail and bar was much greater for the right half of the bars than for the left half, and was considerably greater for the 2,000-lb. bolt tension than for 20,000 lb. For the load at mid-section, the greatest vertical movement between the end of the left rail and the bar was .001 in. for the higher bolt tension and .0015 in. for the lower bolt tension, while for the end of the right rail the movement was .005 in. for the higher bolt tension and .009 for the lower one. This movement gradually decreased to nothing as the load receded from the middle of the joint and the moment at mid-section decreased. The vertical movement at the bar ends on application of load at the mid-section was .002 in. and .007 in. for the two bolt tensions and gradually decreased as the load receded from the middle of the joint.

In the Fifth Progress Report (page 229) tests of rail-joints in the track of the New York Central Railroad with the passage of a wheel load away from the joint are described, but the moments developed along the joint bars were not reported. A summary of the findings of the test in this track may be useful in making comparisons with the results of laboratory tests with advancing load. The moments developed in joints 37 and 43 at mid-section were reported in Fig. 95. Both joints have 38-in. angle bars for 127-lb. rail. Joint 37 evidently had scant supporting reactions by the joint ties and developed a high moment at mid-section; its bolts were not very tight but the bars were fairly well-fitting. Joint 43 had hard tie supports and the moment at mid-section was much smaller; five of the six bolts were loose and there was rather large play between rail and bar. The rear wheel of the loaded car was placed at mid-length of joint and then the car was moved ahead 8, 16, 24 and 32 in. successively. In both joints the moment distribution along the bars for load at mid-length of joint was similar to that found in laboratory tests, if differences in bolt tension and the effect of the second wheel are taken into consideration. For joint 37, the left half of the bars (that is, the half farther away from the inner wheel) was peaked, as has been found in the laboratory tests, for all the positions of load. In the right half, as the load moved along, the moment was less at mid-section than at 2 in. to the right, and the moment at the section 8 in. to the right (although less than the moment at mid-section) decreased much more slowly than did the moment at mid-section as the wheel moved off the joint, thus giving an approach to a straight line distribution in the right half for all positions of the load. A condition somewhat similar existed in the right half of the bars of joint 43. In both joints the sum of the moments in rail and two bars at various sections along the joint agree in form with that observed in the full rail opposite the joint for corresponding positions of the load.

**9. Effect of Combinations of Tight and Loose Bolts.**—Tests were made to find effects of loosening part of the six bolts in angle bar rail-joints. A N.Y.C. rail-joint (No. 5 of the Fifth Progress Report, a worn joint) with 36-in. angle bars and 105-lb. N.Y.C. rail was tested on a span of 74 in. with two loads of 15,000 lb. each, applied at 16 in. from the supports, thus developing a moment of 240,000 in.-lb. throughout the middle 42 in. of the span. A Penn. L-3 rail-joint (No. 1 of this report) with 38½-in. angle bars and 130-lb. P.S. rail was tested on a span of 48 in. with a single load of 33,300 lb. at mid-length of the rail-joint and a maximum moment at mid span of 400,000 in.-lb. Five applications of load were made with all six bolts tight, the initial tension being 15,000 lb. in the N.Y.C. rail-joint and 20,000 lb. in the Penn. L-3 rail-joint.

For the N.Y.C. rail-joint the two end bolts were then loosened and five applications of load made; this was followed with the tightening of the end bolts and the loosening of the two intermediate bolts. For the Penn. rail-joint, after the test with all bolts tight the two intermediate bolts were loosened and five applications of load made; this also was followed by tightening the intermediate bolts and loosening the end bolts and then by making five applications of load.

For the first two or three applications and releases of load after tightening bolts, initial adjustments of the angle bars occur, which may not be particularly significant. With all bolts tight on the N.Y.C. rail-joint, on the fifth application of load the bottom of the bars at their ends moved out slightly and at the middle the bottom moved inward about .002 in. Similarly on the Penn. rail-joint, on the first four applications of load the bottom of the bars at the ends moved very slightly outward at top and bottom, and at mid-length the bottom moved inward a total distance about .004 in. and the top moved very little; on the fifth application there was only slight movement at ends and at middle at the top, but the bottom at middle moved inward .002 in. These lateral movements for a joint with tight bolts are similar to those that have generally been found in the tests with angle bar joints and tight bolts.

With loosened end bolts on the N.Y.C. rail-joint, on the first application of load the ends of the bars moved outward, about .005 in. at their bottoms; at mid-length the bottom of the bar moved inward about .007 in.—not returning fully to the initial position upon release of load. No measurements were made at the top of the bars in these tests of the N.Y.C. rail-joint. Some further adjustments occurred during the following three loadings. On the fifth application of load the ends of the bars moved outward from .001 to .005 in. and the middle inward about .002 in. With loosened end bolts on the Penn. rail-joint, the action was much the same—during the first four applications and releases of load the bottom of the bars at their ends had moved outward, about .005 in., and the middle inward about .002 in. At the same time the top of the bar at the ends had moved slightly outward and the middle of the bars slightly inward. On the fifth application of load, there was but little movement at the ends of the bars. At mid-length the top did not move laterally but the bottom moved inward .001 to .002 in.

With the end bolts tight and the intermediate bolts loosened on the N.Y.C. rail-joint and measurements made on the bottom of the bar only, on first application of load the ends of the bars moved out only slightly, returned nearly to initial position on release of load, moved about the same amount on the fifth application of load, and returned nearly to the initial position; at the middle, on the first application of load the bottom moved inward about .005 in. and went further on more applications of load, finally failing to return to initial position by about .006 in. Little change in position was noted near the intermediate bolts in the applications and releases of load. With end bolts tight and intermediate bolts loosened on the Penn. rail-joint, the adjustment on first application of load included a slight movement outward at the top and bottom of the bars near the intermediate bolts, and the bars did not return to initial position on release of load. On the fifth application of load the only lateral movement was about .002 in. inward at bottom at mid-length. The bottom of the bars at mid-length moved but slightly outward on release of the tension in the intermediate bolts, but on application of load it moved inward as usual.

The vertical movement between rail and bar at middle and ends of bars and at points between was measured in the test of the Penn. rail-joint. Little difference was found in this vertical movement between the three conditions of all bolts tight, end

bolts loosened, and end bolts tightened and intermediate bolts loosened. It should be noted in this connection that the joints had well-fitting bars and that the inner bolts were tight in all cases.

The magnitude of the stresses observed at mid-section and the distribution of the moments for the various sections along the length of the bars were almost the same for the three conditions of bolt tension in the test of the N.Y.C. rail-joint and also in that of the Penn. rail-joint. For the N.Y.C. rail-joint there was little difference in the deflection of the joint bars themselves. For the Penn. rail-joint the deflection of the joint in the span of 48 in. differed little for the three conditions of bolt tension. The differences in restraint of the bars by reasons of all bolts tight or end bolts or intermediate bolts loosened was not large in either joint. The inclination of the neutral axis at the mid-section and the sections within the middle half of the length of the bars did not differ greatly for the three conditions. It should be kept in mind, however, that either the end or the intermediate bolts retained high tension in every test.

Comparison may be made with tests on the same two joints tested at a bolt tension of 2,000 lb. In general the stresses at mid-section were the same as found with the tests just discussed. The moment developed at mid-section of the joint was not changed. The distributions of moments along the length of the bar with the 2,000-lb. bolt tension do not differ greatly in the case of the N.Y.C. rail-joint, but in the Penn. rail-joint the moment distribution diagram is less peaked, indicating that the reactions applied to the bars are located further from mid-length. Deflection of rail-joints under load was not measured in the tests of the N.Y.C. rail-joint. For the Penn. rail-joint the deflection at middle of the span of 48 in. increased from .053 in. for tight bolts to .071 in. with 2,000 lb. bolt tension, owing no doubt in part to the increased vertical and lateral movements between rail and bars observed in the test. These results are similar to the results of tests heretofore reported.

Altogether, these tests may be taken to mean that a loosening of one bolt at one or both halves of a 6-bolt joint does not markedly affect the stresses, vertical movements, and deflections of the joint (though the lateral movement at the end of the bar becomes greater with the end bolt loosened), but that a general low bolt tension will decrease the effectiveness of the joint in various ways. It is evident that an advantage of using six bolts lies in the retention of satisfactory conditions to a greater degree when a bolt in one or both halves has become loose.

**10. The Lateral Springing of the Joint Bars Due to the Application of Bolt Tension and Vertical Loads.**—In applying a given amount of bolt tension it has frequently been observed that the amount of movement of the nut was far greater than any stretch or deformation that could take place in the bolt and threads, especially in the tests where springless washers were used. It seemed logical that the additional spring action must be in the bars. Since elasticity of this nature is desirable in maintaining bolt tension under the wearing and "wedging in" effects of service, tests were made in an effort to find the nature and amount of this springlike movement. Vertical loads were also applied to the rail-joint during these tests to further simulate service conditions.

In considering the results of these tests, it may be well to have in mind in a preliminary way some of the elements affecting the rotation of the nut in wrenching up the bolts. Aside from the frictional resistances to rotational movement the principal resistances to the turning of the nuts may be expected to include (1) stretch of bolts;

(2) distortion of threads and also of nut and bolt head; (3) general inward movement of bar to what may be called its operating initial position, including the overcoming of roughnesses of surfaces; (4) distortion of the vertical section of the bar and the rail due to pressure of bolts and obliquity and eccentricity of rail bearing pressures; (5) local bending of bar longitudinally between points of bearing and of application of bolt tension; (6) general bending of bar along its length in one or many curves due to variations in position of points of contact between rail and bar by reason of variations in fit, camber, lack of straightness longitudinally and vertically, etc.; (7) a twisting movement of the bar because of variations similar to those mentioned in (6). Number (6) is

Fig. 27.—ROTATION OF NUT AND CORRESPONDING BOLT TENSION FOR FOUR FORMS OF JOINT BARS.

probably generally the most productive element in causing lateral spring in heavy joint bars. Of the seven elements, the first two may be considered to produce elastic resistances within the limits of the tests reported. The total stretch of each bolt may be thought of as being roughly .005 in. for a 1-in. bolt having a tension of 20,000 lb. The corresponding movement of the head and nut affects the two bars, probably usually in nearly equal parts, making about .002 in. elastic travel available to each bar from this source. Element (3) may be considered to be inelastic in effect, though the bars frequently became entirely free from the rail upon release of bolt tension. For these tests, elements (4), (5), (6) and (7) may be considered as mainly elastic.

In the first tests (Fig. 27) observations were made on only the rotation of the nut and the corresponding bolt tension when the nuts were wrenched up and loads of 33,300 lb. had been applied five times. The extensometer bolts described on page 114 of the Fifth Progress Report and already illustrated in Fig. 5 were used; these extensometer bolts give a direct indication of the bolt tension. As in other tests, the load was applied at the middle of a span of 48 in. Fig. 27 gives the average results of the observed bolt

tension corresponding to the rotation of the nut in tightening the bolts. Preliminary to these observations, a bolt tension of 20,000 lb. had been applied, the joint loaded five times with a load that developed a bending moment of 400,000 in.-lb. at mid-length (load of 33,300 lb.), and the bolt tension was then released to zero and the nuts turned up snugly. The nuts were then turned by increments of a quarter turn and the amount of the bolt tension recorded up to the tensions shown in the diagram. The diagram includes results of test 2 on N.Y.C. No. 2 rail-joint for 127-lb. rail, test 5 on Penn. L-3 rail-joint for 130-lb. P.S. rail, test 4 on the Norfolk & Western Head Free Continuous rail-joint for 130-lb. P.S. rail, and test 8 for the Santa Fe symmetrical rail-joint for 130-lb. R.E. rail. The first two rail-joints had long bars, 38 and 38½ in., and the last two short bars, 24 and 26 in. long. It should be borne in mind that in these tests springless washers were placed under the nuts.

It will be noted in Fig. 27 that the first part of the rotation of the nut produces little tension in the bolts. To develop a tension of 3,000 to 5,000 lb. requires a rotation of, say,  $\frac{1}{8}$  to  $\frac{1}{4}$  turn with the Santa Fe and N. & W. joints,  $\frac{1}{4}$  to  $\frac{3}{8}$  turns for the Penn. L-3 joint, and  $\frac{3}{4}$  to  $1\frac{1}{4}$  turns for the N.Y.C. joint. To develop a tension of 20,000 lb. requires a rotation of  $\frac{3}{8}$  to  $\frac{1}{2}$  turn for Santa Fe and N. & W. joint,  $\frac{3}{4}$  to  $1\frac{1}{8}$  turns for Penn. L-3, and  $1\frac{1}{2}$  to  $1\frac{3}{4}$  turns for N.Y.C. joint. An increase in tension from 5,000 to 20,000 lb. requires a rotation of about  $\frac{1}{4}$ ,  $\frac{3}{8}$ , and  $\frac{1}{2}$  turns, respectively.

The values given are not entirely definite and only one joint of a kind was tested, but the results may be taken as indications of the movement of bars relative to the stretch of the bolts. As a half turn of the nut corresponds to a movement of about .06 in., the half turn obtained in increasing the bolt tension from 5,000 to 20,000 lb. in the case of the N.Y.C. joint gives a movement about 15 times the increase in stretch of the bolt. In considering the availability of the elastic spring of the bar for readjusting the position of the bar in overcoming wear, it should be borne in mind that for even wear only half of the total movement can be considered to apply to one bar. It is apparent that the movement of the bars through the first part of the wrenching of the nut has little value in maintaining desirable bolt tension in the joint in service and that the movement beyond a minimum tension of, say, 5,000 lb. is the portion having real significance in this respect. It is important also to know what part of the movement through this range may be considered to be elastic and to have "follow up" qualities in order to make it useful in holding the bars in their proper place in the joint.

Tests in greater detail were made with the Penn. L-3 bars (Penn. joint No. 1) in test 7. As the nuts were wrenching up by increments, observations were made of the bolt tension up to 20,000 lb., and the corresponding lateral movements of the joint bars with respect to the rail were also observed. The joint was loaded with a load of 33,300 lb. five times for each change in position of the nuts, and the bolt tension was observed at each position before and after loading. The lateral movements of the top and bottom of the bars at ten points in the length were measured for each bolt tension before and after the application of the five loadings but not while under load. After the loadings had been made at the 20,000-lb. bolt tensions, the nuts were unwrenched by increments and as before the same load was applied five times at each wrenching. Lateral movements of the bars were also measured as before. At zero tension the nuts had failed to return to the original position by about 100° to 200°. In all the joint had been loaded about 55 times during the tests.

The bolt tension corresponding to a given position of the nut is given in Fig. 28 and a summarized (average) value in Fig. 29 for the observed bolt tension after apply-

Fig. 28.—ROTATION OF NUT AND BOLT TENSION DEVELOPED BEFORE AND AFTER APPLICATION OF FIVE LOADS—WRENCHING AND UNWRENCHING—PENN. 38½-IN. ANGLE BARS FOR 130-LB. RAIL.

ing five loads, both for wrenching and unwrenching. In wrenching up, the end bolts took about  $\frac{1}{2}$  turn to reach a tension of 5,000 lb., the intermediate bolts  $\frac{3}{4}$  turn, and the inner bolts  $\frac{7}{8}$  turn. For the change from 5,000 to 20,000-lb. tension each bolt required about  $\frac{1}{3}$  turn, corresponding to a movement of the nut of about .04 in. It will be noted that as the bolt tension is increased the movement of the nut (and likewise of course the movement of the bars toward the rail) becomes smaller. Evidently higher bolt tensions will give smaller and still smaller increases in the movement of the bars and in the amount of springing. It will be noted that for each position of the nut the application and release of the five loads caused the bolt tension in the unloaded joint to fall off, say, 1,000 to 5,000 lb., altogether, though the five applications each time seemed to have nearly exhausted the effect of repetition, indicating that the bars had been forced nearly into final position.

With unwrenching, the descending curves in Fig. 29 are similar to the ascending ones but more steep. In other words, the springing back movement is somewhat less or a part is not immediately available. To reduce the tension from 20,000 to 15,000 lb. involves a rotation of only  $\frac{1}{36}$  turn—a large decrease in tension for a small change in position of nut. In pulling the bar inward during wrenching up, roughnesses have to be overcome and wedging or holding occurs at various points, and these conditions require force to overcome the resistances set up but when overcome part of the spring action becomes available to maintain bolt tension. This is evidenced by the increase in bolt tension observed upon repetition of loading during the unwrenching. It is apparent that

Fig. 29.—ROTATION OF NUT AND CORRESPONDING BOLT TENSION AFTER FIVE APPLICATIONS OF LOAD—SUMMARIZED VALUES FOR WRENCHING AND UNWRENCHING—PENN.  $38\frac{1}{2}$ -IN. ANGLE BARS FOR 130-LB. RAIL.

the curve of available spring movement would lie between the ascending and the descending curves. In Fig. 29 the curves of both the ascending and the descending wrenchings have been drawn through the positions given by the last of the repetitive loadings. The

spring movement in unwrenching shows that elastic springing will be available in holding the bar in place or in moving it toward the rail when the bar wears in service in track.

In Fig. 30 are plotted the relative lateral positions assumed by eight points along the top of the two bars and ten points along the bottom of the bars as the bolt tensions were increased and decreased and loads applied, all taken with respect to the position of the bar before five loads had been applied for a bolt tension of 3,000 lb. in the test just described—the movement of the bars earlier in the test thus being considered a preliminary action in bringing the bars into what may be considered an initial position. The left side of the figure reading down gives positions for increasing bolt tensions (wrenching up) and the right side reading up those for decreasing bolt tensions (unwrenching). The positions shown are those taken after five loads had been applied, except that in the case of 20,000-lb. bolt tension the position both before and after the loadings is plotted. For a given bolt tension the position in wrenching up and in unwrenching may easily be compared.

It will be noted that the bolt tension of 5,000 lb. had drawn the bars inward toward the rail but that little lengthwise bending of the bar has occurred. The measurements before and after application of loads indicate that in the loadings the bars had been drawn somewhat closer to the rail. The position at 10,000-lb. bolt tension shows that the bars have been drawn still closer to the rail, though the total lateral movement of the top of the bar at mid-length is only .002 in. The bending of the bars through their length is apparent. The curvature along the bottom of the bar is a single curve convex toward the rail at mid-length of bar. The curvature along the top of the bar is concave toward the rail at mid-length and convex at the quarter points—a combination of three curves. For the tension of 15,000 lb. the bars have been drawn still nearer the rail except that little or no change has been made at the top of the bar at mid-length. The distinctive curvature along the top and bottom lines of the bars is more marked. The general inward movement of the bar along the bottom is considerably greater than that along the top. At 20,000-lb. tension the changes have continued. With the application of loads the bottom of the bars have been drawn inward still further. The top of the bar at mid-length, however, has changed position but slightly from that taken at the bolt tension of 5,000 lb. The total inward movement of the bottom of each bar between bolt tensions of 3,000 and 20,000 lb. is approximately .020 in. at mid-length and .016 in. at quarter points; the inward movement of the top of each bar at quarter points is .012 in. The inward movement of the ends of each bar at both top and bottom averages about .007 in.

In unwrenching, at 15,000-lb. tension the bars have not fully recovered the position held at the same tension for the wrenching up, though the difference is not great. Further progress in recovery is shown with the bolt tension of 10,000 lb. At 5,000-lb. bolt tension the bars have straightened nearly to their original lines. However, they remain generally .002 to .008 in. closer to the rail along their length, a change that may be due to inelastic action and to breaking down of roughnesses of surfaces. The total amount of the net movement of an elastic springing character for two bars may be taken to be .012 to .016 in., or .006 to .008 in. for each bar.

In the same test of the Penn. L-3 joint stresses were measured at three gage lines at mid-section of the bars to find the stress developed by the bolt tension. For a bolt tension of 20,000 lb. and no load applied, the tensile stresses developed at the top of the bar (points 1 and 2) were 5,000 and 11,000 lb. per sq. in., and at the bottom of the bar (point 8) tensile stresses of 4,000 lb. per sq. in.

The tests described indicate that considerable elastic springing action is brought into play in joint bars by the tension in the bolts, which even for the thick, heavy bars used

Fig. 30.—LATERAL MOVEMENTS OF BARS DUE TO BOLT TENSION AND LOADINGS RELATIVE TO THEIR POSITION FOR A BOLT TENSION OF 3,000 LB.

in the tests must be useful in maintaining tension in the bolts and in holding the bar in place against the rail even after some wear of fishing surfaces occurs. It is apparent that the springing action of bars and rail is a principal source of the maintenance of bolt tension in rail-joints subjected to repeated movements and wear in track. The bending of the bars along their length into one or more curves shows where part of the energy is stored, but other portions may exist in the bending of the vertical section of the bar and the flanges of the rail. The differences found in the magnitudes of the bolt tension at the same position of the bolt in wrenching up and in unwrenching are not wholly inelastic, and the available and usable springing action must lie somewhere between the two curves of Fig. 29. The triple curve along the length of the top of the bar shown in Fig. 30 is quite in contrast with the single curve found along the bottom of the bar. The elastic movement of the two bars at the bolt holes, found to be .012 to .016 in. in this test, is three to four times the stretch in the bolt, the changes being measured from a bolt tension of 5,000 lb. to one of 20,000 lb.

The amount of the springing action naturally will vary with the design of the rail-joint. The four joints tested gave rotation of nuts required to increase the bolt tension from 5,000 to 20,000 lb. in ratios of 1,  $1\frac{1}{2}$ , and 2 for the Santa Fe and N. & W., the Penn. L-3, and the N.Y.C. joints, respectively, but the values obtained from a single joint may not be taken to be generally representative of the characteristics of a type of joint. More tests would be needed to determine fully the characteristics of a rail-joint. It is apparent that the amount of springlike travel of the bars depends in varying degree upon number of bolts, shape and thickness of section, length of bar, camber or lack of straightness, fit, and peculiarities of individual bars. It may be well to note again that no spring washers were used with these joints.

**11. Distribution of Stresses over Vertical Section at and near Mid-Length.**—An important use of the stresses observed in tests of rail-joints in track is the determination of the resisting moment developed in the joint bars by the applied load. In the calculation of this moment the observed stress at two points in the section has generally been used, one near the bottom of the bar and one near its top. For the outer bar stresses have been observed at two gage lines on the upper part of the bar, one near the very top (gage line *A*, Fig. 3) and one farther out from the rail and somewhat lower (gage line *B*), as well as at a gage line toward the bottom of the bar. The presence of the wheel flange prevents measurement at the higher gage line, and so gage line *A* is not usable on the inner bar in tests with locomotives and cars. As reported in the Fifth Progress Report, the stress in the outer gage line (at or near *B*) is relatively smaller than that at the top gage line and its use in the calculations gives a moment that is generally smaller than the applied moment. The deficiency in this observed stress, as compared with the value which would give the actual applied moment, is thought to be due to such matters as the bearing pressure of the rail concentrated on the top fishing surface of the bar at or near the section under consideration, which affects the magnitude of the strain at this point, and also probably to local lateral and vertical bending of the bar at this section caused by eccentricity of the loading applied by the rail to the bar and other factors. To obtain information on the characteristics of different forms of joint bars in these respects and to determine factors similar to those that might be applied to the data of field tests in the calculation of bending moments developed in the joint bars, laboratory tests were made on four Penn. L-3 joints, one Penn. symmetrical joint, and two Santa Fe symmetrical joints. Four of the Pennsylvania joints had been taken from the Pennsylvania Railroad track tested at Claymont. The Santa Fe rail-

joints were of the same section as those in the C. & O. Railway track at Ashland, Kentucky, but the bars were short ones.

The tests generally were made with a single load at the middle of a 48-in. span, but as check tests several tests were made with two-point loading that gave a uniform moment over the middle 36 or 42 in. with the same magnitude of moment as that developed at mid-span in the other tests. Eight to twelve gage lines or more (4-in. or 2-in. or both) were placed at the mid-section of the bars. Generally bolt tensions of both 2,000 and 20,000 lb. were used in the tests. For both forms of loading, the maximum moment developed was 400,000 in.-lb. in two bars at mid-length.

The tests gave general results similar to those in the tests already described. The deflections were somewhat larger for the low bolt tension than for the higher but the stress and its distribution over mid-section were nearly identical for both bolt tensions. The results for the two loads applied were approximately proportional to the moments.

Fig. 31 gives at the upper left for Penn. L-3 joint No. 1 (new or unused joint) the stresses observed over the mid-section plotted with respect to a horizontal gravity axis for an applied moment of 400,000 in.-lb. (two-point loading, average for the two bars). It will be noted that the stresses are generally not proportional to the distances from the horizontal axis, as is indicated by the deviation of the stress curve from the theoretical line. Attention may be called to the difference between the relative magnitudes at the two gage lines near the top of the bar (points 1 and 2); the stress at point 1 is particularly large. The general S-form of the curve is similar to that noted in the Fifth Progress Report. Even when plotted with reference to a favorably inclined axis the stress line was found not to be straight and the stress curve varied considerably from a straight line; it was found that the most favorable position of the axis for reducing the effect of dissymmetry is an inclination of about  $20^\circ$  with the horizontal. Of course, the change of inclination of axis does not entirely eliminate the S-shape.

A contrast to this stress curve is seen in the stress curve shown at the upper right in Fig. 31, which is the plot of the results of the test of the same joint when the rail ends were separated by a gap of  $14\frac{1}{4}$  in. and bolts were placed in the end holes of the bars only (high bolt tension used) and a two-point loading applied as in the other test. It is seen that the stress curve is fairly straight and differs little from the calculated stress line based on the usual stress analysis; if plotted with reference to an axis having an inclination of  $9^\circ$  the agreement of the observed and the calculated values is remarkably close. The separation of the two rails has left the mid-section free from the application of concentrated bearing pressure by the rail. These differences and whatever restraint is applied to the bars by the rails has produced a resulting straight-line distribution of stress over the vertical section. It is plain that for the regular set-up of the joint the lack of proportionality between stresses at different gage lines is something that must be taken into account in making calculation of resisting moments developed in the joint bars.

At the lower part of Fig. 31 are given the stress distribution curves at mid-section for bars from joints 11 and 5 of the test track at Claymont. The distribution does not differ greatly from that of joint 1. The curves have a marked S-shape and this shape is found to be retained even when the stresses are plotted with reference to an inclined axis. An axis inclined about  $20^\circ$  straightens out much of the jaggedness, but an S-form remains.

In the upper left of Fig. 32 the stress distribution at mid-section is given for the Penn. symmetrical bars taken from joint 2 of the track at Claymont. The value of the

stresses at the two top gage lines are close to the analytical ones but that at the lowest gage line is slightly smaller. As would be expected, the S-form is more marked in the top portion than in the lower part. The stress curve is free from the jaggedness found in unsymmetrical bars.

Fig. 31.—OBSERVED STRESSES AT MID-SECTION FOR  $38\frac{1}{2}$ -in. PENN. L-3 JOINT BARS FOR 130-LB. RAIL—ALSO TEST WITH RAIL ENDS SEPARATED TO MAKE A GAP OF  $1\frac{1}{4}$  IN.

In the lower left of Fig. 32 the stress distribution at mid-section is given for the Santa Fe symmetrical joint No. 1. The values for joint 2 are almost identical with those of joint 1. Here again the same general form of curve exists. The deviation from the theoretical stress line is more in the upper part where the main effect of bearing pressure may be expected to be, and smaller in the lower part. The application of a negative load having the same magnitude as the positive (see lower of the figure) gives

a similar stress curve but oppositely disposed. The rail bearing pressure near mid-length of bar is, of course, on the bottom of the bar and the greater divergence from straight line relation is in the lower portion of the section as is to be expected.

Fig. 32.—OBSERVED STRESSES AT MID-SECTION FOR  $3\frac{1}{2}$ -IN. PENN. SYMMETRICAL JOINT BARS FOR 130-LB. P.S. RAIL AND AT SECTIONS 8 IN. AWAY, AND AT MID-SECTION FOR 26-IN. SANTA FE SYMMETRICAL JOINT BARS FOR 130-LB. R.E. RAIL FOR POSITIVE LOAD AND NEGATIVE LOAD.

The gage lines used in all these tests naturally were placed on the surface of the bar away from the rail. It is apparent that the stresses may be different on the opposite surfaces and also at points within the bar. The purpose of these tests, however, was to throw light on the relation between the stresses at places where gage lines would be accessible in the track and to make a comparison of the moments calculated therefrom with the magnitude of the moment applied to the bars.

The data of such tests as those just described may be utilized to find conversion ratios by which the moment calculated from the observed stresses may be converted or corrected to agree more closely with the value of the moment applied to the joint. In Tables 3, 4 and 5 values are given of the ratios between the moments calculated from

the stresses observed at two given gage lines (such as gage line *A* and gage line *C*) and the applied moment. The calculated moments were computed by equation (67), which is given in Article 4 "The Function and Action of the Rail-Joint," using the observed stresses and the coordinates for the two gage lines used. A column is also given for the ratio of the moment obtained by the use of two gage lines (such as *A* and *C*) to that obtained by the use of *B* and *C*.

The location of the gage lines on the section of the bar is shown in Fig. 31 and 32. In Table 3 joint 1 is the joint that was used in the general laboratory tests reported in the previous articles. In joints 11, 5, and 1 (lat. def.) the bars taken from the joints having the same number in the track of the Pennsylvania Railroad at Claymont were

TABLE 3

Ratio between the Moment Calculated from Two Observed Stresses and the Applied Moment; Also the Ratio of the Moment Calculated from *A* and *C* to the Moment from *B* and *C*—All for Mid-Section—Penn. L-3 Rail-Joints for 130-lb. P.S. Rail

Test 11 and 12 of joint 1 and test 1 of joint 11 are two-point loading; all others are one-point loading. The first two lines for test 3 of joint 5 use values of 4-in. gage readings taken on plugs projecting  $\frac{1}{4}$  in. and likewise the first two lines of test 4 values on plugs projecting  $\frac{1}{2}$  in. Bolt tensions are 20,000 lb.

TABLE 4

Ratio between the Moment Calculated from Two Observed Stresses and the Applied Moment; Also the Ratio of the Moment Calculated from A and C to the Moment from B and C—All for Mid-Section—Penn. Symmetrical Rail-Joints for 130-lb. P.S. Rail

Tests are single-point loading. The first two lines for the 4-in. gage values in both test 3 and test 4 were taken on plugs projecting  $\frac{1}{4}$  in. Test 3 was made with low bolt tension; test 4 with high bolt tension.

used in the laboratory tests; the bars of joint 1 (lat. def.) were deformed laterally as described in Article 7b "Penn. Rail-Joint for 130-lb. P.S. Rail." The bars of Table 4 were the pair of Pennsylvania symmetrical bars taken from joint 2 at Claymont. The Santa Fe symmetrical bars of Table 5 were the bars used in tests reported in Article 7d "Santa Fe Symmetrical Type Rail-Joint for 130-lb. R.E. Rail."

It is of interest to note that test 12 of joint 1 (a Penn. L-3 joint for 130-lb. P.S. rail), which had the rail ends separated by a gap of  $1\frac{1}{4}$  in. and which shows a straight line stress distribution over mid-section in the upper right in Fig. 31 as described earlier in this article, has values of conversion ratios applicable to moment calculations that are very near to unity. (See Table 3). This is a further corroboration of the correctness of the methods and formulas used in this report for converting or correcting the moments calculated from the observed stresses to agree more closely with the value of the moment applied to or developed in the joint—a conversion necessitated by the disturbing effect on the stress at certain gage lines at the top of the bar made by the load bearing pressure of the rail near its end.

In certain tests of Tables 3 and 4 small plugs were screwed into the bar at the location of the gage points in such a way as to extend away from the surface of the bar  $\frac{1}{4}$  in. or  $\frac{1}{2}$  in. and gage holes were drilled in their outer ends at points corresponding to the usual gage points and the gage measurements were taken for these gage lines; the purpose was to reproduce the positions of the points of measurement made in the field tests at Claymont with the Westinghouse magnetic strain gage and to furnish comparisons with measurements made at gage points at the surface of the bars.

In the several combinations of gage lines referred to in the tables, the same lower gage line is used, but different gage lines are used as the higher gage line of the combination. It will be noted that for each combination of gage lines, the ratios given in each of the three tables are fairly uniform and consistent. The ratios for the high points of the bars and 2-in. gage lines are generally greater than unity, and those for the gage lines farther from the rail and lower in position are smaller than unity. The ratios for the 2-in. gage lines are generally larger than for the 4-in. gage lines, and even for the high gage line the values given are generally somewhat greater than unity. The ratios for the upper gage line that is away from the rail (like *B* and 3) are considerably less than those for a gage line close to the top point of the bar.

The ratios in the fourth column for both 2-in. and 4-in. gage lines are all greater than unity. They show the relative discrepancies in using either one of the two positions of an upper gage line and the need of a conversion factor.

For the Penn. L-3 bars the difference between the ratios found with readings on the plugs and those on the surface of the bar vary with the gage line considered. The ratio of *A* and *C* to *B* and *C* is greater with plugs than without. For the symmetrical type of bar the corresponding values with and without plugs do not differ much.

The ratios given for the negative moment in one combination of gage lines is smaller than those for positive moment and in others it is larger or not greatly different.

Attention is called to the fact that ratios calculated from the stresses observed in the test made with the rails separated some distance (stresses shown in upper right of Fig. 31) approximate very closely to unity (see Table 3). This is equivalent to saying that the stress distribution at mid-section given in the figure is nearly a straight line.

The three tables give interesting information on the differences in calculated moments obtained with stresses observed for gage lines at different positions. It is not to be expected that the values given in the tables will be applicable directly and accurately to

finding the correct value of the moment developed in the bars of the joints in the track, for the track joints are subject to unknown lateral bending (both bending of individual bar and bending of the joint as a whole) and the position and amount of the application of bearing pressure in the track may differ for different joints, whereas in the laboratory the conditions imposed are fairly uniform in all the tests. However, the values in the tables will be found useful in interpreting tests of the rail-joints in track.

In tests of Penn. symmetrical joint (test 1 and 2) stresses were measured at two sections 8 in. each way from mid-section, which throw light on the variation in stresses in a section away from pressure bearing areas existing near mid-section. The 4-in. gage lines 1, *A*, *B* and *C* (see Fig. 32) gave stresses which are plotted at the upper right of the figure, the open circle representing the observations at 8 in. to the north of mid-section and the solid circle 8 in. to the south—the two tests being reported. Lines connecting the four points are close to the analytical stress distribution for pure flexure. Although no gage lines were used near mid-depth of section it is probable that the stress line does not deviate far from a straight-line distribution. It is evident the section is far enough away from the top bearing pressure to be unaffected by these pressures. The results are similar to those observed in the test of a rail described in the Fifth Progress Report, page 189.

The calculation of the moments developed in rail and bars at these two sections from the observed stresses shows that the sum of the moment developed in the rail and that in the two bars is about 260,000 in.-lb., which is close to the magnitude of the applied moment at these sections. Of this sum, 155,000 in.-lb. is taken by the rail and 105,000 in.-lb. by the two bars. The moment developed in the bars in these tests is about .40 of that developed at mid-section. The foregoing values were calculated from stresses at gage lines *A* and *C*. The use of stresses at *B* and *C* or at 1 and *C* would give somewhat larger values of the moment at the two sections.

**12. Deflection of Rail-Joints and Joint Bars.**—In the laboratory tests of rail-joints observations were made of vertical deflections of both joint bars and rail-joint as a whole upon the application of load. Table 6 gives some of the results. The joints have been described elsewhere. I.C. joint No. 3 (90-lb. rail) was somewhat worn. The other joints may be called well fitting, except the Santa Fe joint, which had some looseness in one half, a condition which partly accounts for the higher value of its ratio in the table. The values given are the deflections for the last of five repeated loadings (except where a first loading is indicated) and do not include any play that might be found between a negative and a positive load, except in the case of the Muller joint. The span was 48 in. and a single load was applied at the middle, except where otherwise noted; the exceptions are the Continuous joints, which had two-point loading. Under the heading "Rail-Joint" are given (a) the observed vertical deflection of the rail and rail-joint at the middle of the span used, (b) the calculated middle deflection for a full rail with the same span and loading, and (c) the ratio of (a) to (b). This ratio enables comparisons to be made in terms of the deflection of full rail. The closeness of this ratio to unity is an indication of the ability of the rail-joint to distribute load over a number of ties as compared with the action of full rail. The columns under "Joint Bars" give the middle deflection of the joint bars from end to end, whether the bar is short or long. "Top" refers to a line along the top of the bar and "Bottom" to one along the bottom. It will be noted that the deflection of the rail-joint when low bolt tension is used is considerably greater than for high bolt tension, due principally to the increase in play between rail and bars with low bolt tension. The deflection of the joint

TABLE 6

## Observed Vertical Deflection of Rail-Joints and Joint Bars

\*Two-point loading was used with spans of 74 in. and 68 in. for the N. & W. head-bearing and head-free joints, respectively. The two loads were applied 16 in. from the supports and produced a moment of 400,000 in.-lb. between the points of application of the load. In all other tests the load was applied at the middle of a span of 48 in.

†The upper value is for a line along the outer edge of the bottom of the reflexed flange and the lower for one along the inner edge.

‡First loading.

bars is also greater for low bolt tension than for high bolt tension. This may be due partly to the greater distance between the resultants of the reaction forces and the position of the bearing pressures when the tension is small and partly to the smaller restraint and the greater inclination of the neutral axis with low bolt tension. The differences in the deflection of the Head Free Continuous joint for lines along the top of the bar, along the outer edge of the bottom of the reflexed flange, and along the inner edge of this flange is an interesting phenomenon. It is evident that the section of the bar does not act integrally during bending. The deflections for negative load upon fifth application are nearly proportional to those for positive load except for the Muller joint. In this joint the first application of negative load gave very large deflection and there was considerable play between the position of the joint bars under positive load and that under negative load, quite in contrast with the corresponding movement of the other forms of joint. The magnitude of the deflection of the Muller joint under positive load from a position where play is overcome is much greater than for the other joints.

Although the method of supporting the joints in these laboratory tests is far from being the same as the support given by the ties in track, the form of the moment curve is not greatly different and the information here given has value in making comparisons. It should be added that for joints having play between bars and rail the deflections become very much greater.

Observations were also made on the lateral deflection in the length of the joint bar. Although the lateral deflection was small, its magnitude with reference to a chord along the bottom of the angle bar was considerably greater with low bolt tension than with high bolt tension. For the symmetrical bars, the deflection was very small with high bolt tension and larger with low bolt tension—the increase in the latter case being due to the outward movement of the bars at their ends by reason of the long distance from the end bolt to the end of the bar in this 4-bolt joint. The lateral deflections observed in the tests ranged from 0 to .012 in.

### III. TESTS OF RAIL-JOINTS ON THE PENNSYLVANIA RAILROAD

13. **Purpose of Tests and Arrangements Therefor.**—All the previous tests of rail-joints for obtaining stresses and movements in the joint bars were made with static loading. It has been thought by some engineers that the action of the rail-joint under moving load at train speeds must be far different from that under static loading, that the approach of the wheel load would produce stresses and movements in the joint bars and bolts quite different from those found in static tests, and that at high speeds of the moving load stresses of much greater magnitude are developed. Accordingly, at the first opportunity arrangements were made to measure stresses in the joint bars of rail-joints in track and the tension produced in the joint bolts through the application of moving wheel loads at various speeds.

The principal obstacle in the way of making measurements of stresses in rail-joints under moving loads had been the lack of an instrument which was suitable for the purpose. The stremmatograph that had been used in measuring stresses at base of rail could not be applied to the joint bars to measure stresses at more than one gage line on a section of the bar, while gage lines at two or more points in the section of the bar are needed to obtain the data necessary for computing the bending moment developed in the joint bar. No instrument applicable to the rail-joint in track and recording the stresses developed under such conditions was available. The Westinghouse Electric and Manufacturing Company for several years had been developing an instrument for measuring stresses on pieces or parts when subjected to the action of moving loads; the records of the stresses made by the instrument are produced on photographic films through the agency of the oscillograph, which is placed in a shelter at some convenient point on the railroad right-of-way. This instrument, known as the Westinghouse magnetic strain gage, had been found to give definite and accurate records when used to measure stresses in rail at train speeds without being seriously affected by the vibrations of the rail even at the highest speeds used. In order to take advantage of this type of instrument for tests of rail-joints in track, suggestions were made to the Westinghouse Company on the form and dimensions and restrictions needed for a magnetic strain gage suited to the joint bar, and other help given. The engineers of the Westinghouse Company then designed and developed a compact form of magnetic strain gage, which with certain limitations may be attached to the joint bar at different places and gives accurate and trustworthy records of stress at high train speeds. The auxiliary equipment used with the magnetic strain gage is elaborate and expensive, but its use has proved it to be a satisfactory and reliable apparatus for measuring and recording stresses under moving loads. Before making moving load tests on rail-joints, the staff of the Committee designed and developed and calibrated special extensometer bolts to which the special magnetic strain gage could be applied for determining changes in tension in the joint bolts which might occur upon the application of a moving load at train speeds. This apparatus was found to be accurate and satisfactory and well fitted for the purpose.

During September and October, 1930, the staff of the Committee participated in tests of track of the Pennsylvania Railroad on its electrified section at Claymont, Delaware (near Wilmington), cooperating with the Pennsylvania Railroad and the Westinghouse Electric and Manufacturing Company. The tests were carried out primarily to determine the action and characteristics of certain new types of electric locomotives being built for the Pennsylvania Railroad. In these tests measurements of stresses in rail and in rail-joints under the load of moving electric and steam locomotives and cars were made up to high rates of speed, using the equipment referred to above. With the elec-

tric locomotives runs at speeds as high as 100 miles per hour were made. With a steam locomotive, speeds as high as 90 miles per hour were used. The data on the stresses developed in the rail at the various speeds and under the varied conditions of the different runs have been used by the Westinghouse Company in a study of the action of the locomotives at the high speeds.

The data on the stresses developed in rail-joints have been used as the basis for the study of rail-joints given in this chapter. Only the electric locomotive and cars were used in the tests of rail-joints. Speeds of 5, 45, and 70 miles per hour were made in the tests of rail-joints, with a few runs at 90 miles per hour. Most of the tests were conducted on rail-joints of angle bar type  $38\frac{1}{2}$  in. long, but angle bars of the same section 24 in. long and bars of symmetrical type  $38\frac{1}{2}$  in. long were used. It is well to note that the track on the test stretch is heavy, stiff, high-grade track in excellent condition and especially suited for high speed and heavy traffic.

**14. The Track.**—The tests on the Pennsylvania Railroad were conducted on the southbound passenger track (No. 4) one half mile south of Claymont, Delaware, on the Maryland Division. The stretch used in the tests was the straight track at catenary pole marked 20.03 miles from Philadelphia. At the special test stretch of track new rail, new ties, and other new track materials were applied for about three rail lengths and the track brought up to standard ballast section and to new line and surface two months before the tests. The rail was 130-lb. P.S. section, 39 ft. lengths, rolled in April 1930. The ties were new sawn ties of treated oak and gum mixed, well graded as to size, 7 by 9 in. by 8 ft. 6 in., and laid 22 to the 39-ft. rail. On the prepared track the ties were well spaced, the spacing center to center of the three joint ties in almost all spacings being 19 or 20 in. The ties away from the joint were fairly well spaced, 90 per cent being spaced between 20 and 24 in. The tie-plates were heavy duty Pennsylvania standard, 7 by 14 in., with an eccentricity of  $\frac{1}{2}$  in. and without inclination. A driven spike in the outer and inner portions of the tie-plate attached the tie-plate to the tie independently of other spikes at the inner and outer edges of the base of rail through each plate—four driven spikes to the tie-plate. There were four Stead rail anchors to the rail length. The depth of the stone ballast below the bottom of the ties was 7 in. Beneath this for a considerable depth was a combination of stone, gravel and cinders. The entire track had been raised during the spring of 1930. The track at the test location was on a fill of 3 ft. The gage as measured during the tests was  $\frac{1}{8}$  in. close. The grade was very light.

Fig. 33 shows the position of the prepared track with respect to the other three tracks and also the joint locations at which tests were made and their designation by numbers. The position of the shelter house where the auxiliary equipment was placed is also shown. Joint locations 1, 3, and 5 were in the west rail and joint locations 2 and 4 were in the east rail. At the time the new rail was laid in July these five joint locations were equipped with the Pennsylvania standard L-3  $38\frac{1}{2}$ -in. 6-hole angle bars,  $1\frac{1}{8}$  by  $6\frac{1}{8}$ -in. Pennsylvania standard bolts with Pennsylvania standard helical spring nut locks. The section of the L-3 angle bars is given in Fig. 3. The Pennsylvania symmetrical form of joint bar used in the tests is described in Article 7c, the section given in Fig. 3 and its properties in Table 2.

Joint location 9 was 60 ft. south of the special test stretch. The rail at this point was laid in 1928. The tie-plates were 7 by  $10\frac{1}{2}$  in. and the L-3 angle bars were 24 in. long. As the electrical leads were long enough to reach over to track No. 1 (northbound passenger) a joint was selected at joint location 11. Here there were 130-lb. P.S.

rail laid in 1929, tie-plates  $7\frac{1}{2}$  by 14 in. on the three joint ties and 7 by  $10\frac{1}{2}$ -in. tie-plates elsewhere, and standard L-3  $38\frac{1}{2}$ -in. angle bars. The track was good but not up to the conditions found on track No. 4.

The track at the special stretch was in excellent line and surface and each tie appeared to be in condition to take its share of load and the play between rail and tie bed reasonably uniform. At the highest speeds, the test locomotive had less lateral sway in passing over the special stretch than at points on either side.

*The location of the joints tested is designated by numbers.*

Fig. 33.—SKETCH SHOWING RELATIVE POSITION OF PREPARED STRETCH OF TEST TRACK AND RAIL-JOINTS TESTED ON THE PENNSYLVANIA RAILROAD NEAR CLAYMONT, DELAWARE.

A few hurried measurements of track depression (under the wheels of locomotives and cars) were taken to estimate the stiffness of the track and the value of the modulus of elasticity of rail support,  $u$ . The track structure was very stiff; the incomplete data taken indicate a value of the modulus in the neighborhood of 4000 lb. per in. per in.

The measurement of rail stresses on straight track by the Westinghouse Company to determine the action of the locomotives at various speeds was made at a place between joint locations 2 and 3.

**15. The Locomotive and Cars.**—As the tests on rail-joints were made to study rail-joint characteristics rather than locomotive differences, only one locomotive was used—electric locomotive 7850 of the 0-1 type. At the time the tests were made, multiple-unit passenger cars were used for the local passenger trains and the first of the 0-1 type locomotives were being tested out in service. Steam locomotives were still operating freight trains and through passenger trains.

The 0-1 type locomotive (passenger service) has two pairs of driving wheels (diameter 72 in.) and a four-wheel truck at either end. Fig. 34 gives the nominal wheel loads and wheel spacings of the locomotive. The rigid wheel base is 10 ft., the spacing between drivers. The frame supports a single cab that extends the whole length of the locomotive. Roller bearings are provided for the motor armature bearings, the driver axles, and the axles of the trucks. The power supply was alternating current of 11,000

volts and 25 cycles from an overhead line. Two twin armature motors of 1,060 h.p. each, mounted above the driving axles, drive the wheels with gears and pinions through the medium of a link type drive. Marked improvements in the design of the single phase alternating current motors have permitted the placing close to the driving axles of motors with sufficient power to give high tractive force without the use of side rods. The speed is controlled by varying the voltage on the motors.

Fig. 34.—DIAGRAM OF WHEEL LOADS AND WHEEL SPACING FOR PENNSYLVANIA ELECTRIC LOCOMOTIVE 7850.

In test (e) the electric locomotive pulled four loaded coal cars. The first car behind the locomotive was a 50-ton car loaded to give an average load per wheel of 16,500 lb. The truck wheel spacing was 5 ft. 6 in. and the distance between interior truck wheels 16 ft. 9 in. The second car was a 70-ton inboard Timken roller bearing car with a truck wheel spacing of 5 ft. 10 in. and a distance between interior truck wheels of 26 ft. 2 in., loaded to give an average wheel load of 24,500 lb. per wheel. The third car was a 70-ton car of the same class and dimensions as the second except that it had plain bearings—the weight per wheel was 24,500 lb. The fourth car was a 90-ton four-wheel truck car (the only one of this class owned by the Company) with a truck wheel spacing of 5 ft. 8 in. and a distance of 32 ft. 4 in. between interior truck wheels—the average weight per wheel was 30,400 lb. The spacing between end wheels of two coupled cars was 6 ft. 9 in.

16. **The Magnetic Strain Gage and Its Auxiliary Equipment.**—The magnetic strain gage\* developed by the Westinghouse Electric and Manufacturing Company consists of two U-shaped laminated cores ( $U_1$  and  $U_2$ , see Fig. 35, a schematic longitudinal cross-section, in which the hatched areas represent parts that are connected to the right-hand fastening and the unhatched areas are connected to the left-hand fastening) fixed with respect to each other and wound with coils designed for the high frequency excitation used and a laminated armature (A) that moves in the gap between

\* For further description of the Westinghouse magnetic strain gage and its use, see "A Magnetic Strain Gage" by J. Paul Shamberger, *Proceedings, American Society for Testing Materials*, Vol. 30, p. 1041 (1930), and "Rail Stresses and Locomotive Tracking Characteristics Found in Tests on the Great Northern Railway," by J. Paul Shamberger and B. F. Langer, *Bulletin 339, A.R.E.A.*, September 1931. The original conception for this instrument is credited to J. G. Ritter. It is understood that improvements in the construction of the magnetic gages and their operation have been made since the tests were made at Claymont.

the U-cores to an amount corresponding to the strains occurring between the points of attachment of the instrument. The movement of the armature when the development of a strain changes its position with respect to the pole faces of the cores decreases the gap on one side of the armature, and increases it on the other, and thus changes the reluctances of the two magnetic paths and unbalances the voltage drops in the circuits. In the operation of the magnetic strain gage one oscillograph element (see Fig. 36 showing the lay-out of the electric circuit) is connected between the coils in such a manner that the unbalanced voltages send a current through the element that is proportional to the movement of the armature. This proportional relation will hold for a sufficiently large movement of the armature to indicate any stresses normally encountered. The oscillograph record thus gives values that are proportional to the strains.

Fig. 35.—DIAGRAMMATIC REPRESENTATION OF WESTINGHOUSE MAGNETIC STRAIN GAGE.

Fig. 36.—LAY-OUT OF ELECTRIC CIRCUITS OF MAGNETIC STRAIN GAGE EQUIPMENT.

As has already been mentioned, the instrument that had already been used by the Westinghouse Company in tests of rail stresses, which had an 8-in. gage length and had given excellent satisfaction, suggested the advantage to be gained by the design of a strain gage having a shape and dimensions suitable for making tests of rail-joints. The appearance of the magnetic strain gage of 4-in. gage length thus developed is illustrated in Fig. 37. Telescoping aluminum cylinders about 1 in. in diameter enclose the coils, laminated pole pieces and armature. The working parts of the strain gage are attached

to the enclosing cylinders in a manner which permits a movement of the parts sufficient to cover the strain cycles. A tolerance for variation in the distance between the studs on which the strain gage is mounted is separately provided. An outer cylindrical casing protects the instrument from weather and dust. In Fig. 37 it has been rotated to show some details. For use in mounting the strain gage, two No. 19 holes are drilled about  $\frac{1}{4}$  in. deep and 10-32 threads tapped in the joint bar at the position selected, and studs screwed into the holes. These studs have spherical surfaces at the contact areas to minimize any jamming effects of small misalignments of the studs.

Fig. 37.—VIEW OF 4-IN. MAGNETIC STRAIN GAGE USED IN TESTS OF RAIL-JOINTS.

The auxiliary equipment is somewhat varied and complex. The principal auxiliaries are the oscillographs which record graphically the stress variations on photographic films. In the tests on the Pennsylvania Railroad two six-element portable oscillographs were used simultaneously, with the rotating drums containing the films driven by a common shaft and run by one motor. Thus both record films had identical scales of the distances representing the locomotive movement along the track.

To supply current for the instruments and field excitation for the oscillographs a high frequency motor-generator set was used. The equipment required about 150 watts per instrument, most of this being used in the oscillograph field circuit. The gages are connected in parallel and require about 10 volts at 750 cycle frequency. A power supply of 5 kilowatt capacity was needed for the tests but this was larger than would have been necessary if a motor-generator set had not been required to furnish direct current for the high frequency motor-generator set. Since the high frequency supply (750 cycles) was at 120 volts a high frequency transformer was required to supply the proper voltage for the gages. The oscillograph fields were connected in series to the 120 volt 750 cycle supply. It was necessary to have condensers of sufficient capacity in the oscillograph field circuit to obtain similar phase relations for the current in the oscillograph fields and that in the oscillograph elements. This condenser capacity aids in adjusting the current in the oscillograph element to a minimum value and reduces the width of the stress line. When the voltage was removed from the oscillograph fields a

shunt load was automatically placed on the high frequency generator. This reduced speed and voltage variations that would have occurred if the load had been entirely removed.

The oscillograph elements were damped in such a manner that they would not be susceptible to high frequency vibrations but would still indicate correctly the stress variations. As a check on the accuracy of the damped elements, an undamped element was used for several runs. Little if any difference was noted. The damped elements were considered accurate up to variations of stress of 200 cycles per second.

For the higher speed runs a track switch operated by the passage of the locomotive started the oscillograph motor. This placed the records more accurately and conserved film.

Ten inches of the film length were used for each run with the electric locomotive. The drum was rotated about 14.5 seconds for 5 miles per hour, 1.70 seconds for 45 miles per hour, and 1.1 seconds for 70 miles per hour. It was necessary to have the record continue some distance ahead and behind the locomotive in order to locate the zero line of stress. The oscillograph was capable of registering with much higher speeds of rotation of the drum but sufficient separation of stress peaks was obtained at these speeds to show the stress variation accurately.

As mentioned previously the strain gages were attached to studs screwed into holes that had been drilled and tapped in the joint bars at the location selected. The strain gages are adjustable for some variation in distance between the studs. This variation was minimized by using jigs for drilling the holes for the studs. After attachment a total air gap sufficient to record the maximum stress variation (about .030 in.) was set between the two pole pieces and the armature. The armature was adjusted to a central position and locked. These adjustments of distance were all made with the aid of thickness gages. With the strain gages thus adjusted and parts locked in the recording position the power was turned on and the zero stress position of the oscillograph element adjusted so that each gage would indicate in the proper place on the film and have sufficient space to produce its record without interference with the others. The film used for each oscillograph was 7 in. wide and 30 in. long and ordinarily recorded three runs of the locomotive. There were six records of stress on each film and one film had a 60 cycle timing wave at one edge in addition to the six stress records. The timing wave record was useful in obtaining a check on the speed of the locomotive as indicated by the speedometer.

The calibration of the gages was done in the field before and after the tests of the rail-joints, and at other times for check purposes or when instruments had been re-adjusted or connections transposed. The gages were detached from the studs and mounted one at a time on a calibration device which measured on a dial the movement of the armature due to turning a threaded shaft. Deflections of the oscillograph element due to this movement were recorded on the film in the oscillograph drum, thus giving a permanent record of the calibration. This calibration was the overall constant for the gage and oscillograph element; any rearrangement of the gage connections or change in the total amount of air gap necessitated a new calibration. The constant was ordinarily about 25,000 lb. per sq. in. stress for 1 in. deflection on the film, though the range on the original film records was from 16,000 to 45,000. Calibrations taken at various times checked quite well.

The sensitivity used was by no means the greatest that could have been obtained but was considered the best for the purpose. The accuracy obtained was apparently

limited only by the closeness to which the deflections on the film could be read except in a few cases where some looseness in the adjustments caused vibration and a jagged record. If the deflections on the film were read accurately to .02 in. the stresses would be accurate to about 500 lb. per sq. in.

The cables used to connect the twelve instruments with the oscillographs altogether made up a considerable length. The arrangement was such that the instrument could be placed along a stretch of 300 ft. of track without moving the shelter building which housed the oscillographs and contained a dark-room for film development.

The same 4-in. magnetic strain gages were applied to special extensometer joint bolts (described in Article 22) and indicated satisfactorily the changes in bolt tension at the various speeds.

**17. Conduct of Tests and Reduction of Data.**—One purpose of the tests of rail-joints was to determine the magnitude of the moments taken by the joint bars at mid-section at train speeds. To accomplish this it is essential either that the gage lines be placed at points in mid-section where the measured strains represent the flexural stresses in the joint bar acting as a beam, or as in the case of the inner joint bar where the magnetic strain gage can not be applied to measure directly the real flexural stress in the top portion that a method be available which will permit an allowance to be made in the calculations for the effect of bearing pressure upon the strain at the gage lines. To utilize such a method it is necessary that three gage lines be used at the mid-section of the outer bar. In Fig. 38 are shown the positions of the five instruments

Fig. 38.—POSITION OF FIVE MAGNETIC STRAIN GAGES AT MID-SECTION OF JOINT BARS.

used at mid-section, and in Fig. 39 a view of six instruments in position on a rail-joint. The magnitudes of the stresses at gage lines *A* and *C* may be used to calculate the bending moments developed in the joint bar by the methods outlined in Article 15 "Methods of Calculations", of the Fifth Progress Report and referred to in Article 4 of this report. By using the measurements at *B* and *C* with either the stress deficiency method or the lateral bending-conversion ratio method (to be described in Article 19 of this report) reduction values for determining moments from *B* and *C* may be obtained which when applied to *B* and *C* of the inner bar in the calculation will give fairly representative values of the moment developed in this bar. The number of magnetic strain gages used was limited to twelve, the number of elements in the two oscillographs. Besides the five at mid-section the instruments were placed to make measurements of stress at sec-

tions 8 in. each way from mid-section. For one of these sections instruments were placed at *A* and *C* on the outer joint bar and at *B* and *C* on the inner one, and for the other section they were placed at *A* on the outer joint bar and at *B* and *C* on the inner one.

In the tests to determine changes in bolt tension six of the magnetic strain gages were used on the six extensometer bolts and five magnetic strain gages were placed at the five gage lines at mid-section as previously described.

Fig. 39.—VIEW OF SIX MAGNETIC STRAIN GAGES IN POSITION ON A RAIL-JOINT.

Constants by which the record of each magnetic strain gage on the film of its corresponding oscillograph element may be converted into stress were obtained by calibration at the test location before, during, and after the tests on the rail-joints, with check calibrations at other times when thought desirable. The films were developed in the dark-room of the shelter building immediately after their exposure.

Except for the most important trains the traffic was diverted from the test track, leaving it free for the conduct of the tests. For a given rail-joint, the usual procedure was to make three or four runs at 5 miles per hour, then the same number at 45 miles per hour, followed with three or four runs at 70 miles per hour, with sometimes one or two at 90 miles per hour, and sometimes additional runs at one speed or another. The speeds were read from the speedometer in the cab of the electric locomotive. The speedometer had been checked with a stop watch in runs over a measured stretch of track and the reported speed was also checked by the timing wave on the oscillograph film.

The tests were made on several rail-joints—in their original condition with bolt tension as found, with joint bars removed from their original joint location and placed

at other joint locations, and with other variations. In Table 7 information is given on the conditions of the joint bars and the designation of the various tests with remarks on the bolt tension, time of installation, etc. (The tensions found in individual bolts of the various joints are given in Table 14 and 15.) See also Fig. 33 for joint locations. Joint 4 was first tested in its original condition with the existing bolt tension (called joint 4-4, meaning joint location 4 and joint bars as found in the track at joint location 4 and its test designated as (a)); then tests were made on the same joint with the tension reduced to 2000 lb. in each bolt (test (b)). The 38½-in. L-3 angle bars of this rail-joint were then cut to a length of 24 in., placed back in track at the same joint location, and test (c) was made on the modified joint 4 still numbered as joint 4-4. Joint 5-5 (joint location 5 and bars 5 as found in the track) with 38½-in. L-3 angle bars was found during test (f) to have the tie-plates at its three joint ties reversed in position from end to end, thus reversing the position of the eccentricity of the tie-plate. As the next tie-plates were laid normally the rail and rail-joint was subject to some twisting action under load. After the tests on this joint had been made the bars were placed at joint location 4 (called joint 4-5) and further tests made, both with the electric locomotive running light (test (d)) and with a train of four heavily loaded cars (test (e)). The laterally deformed angle bars were tested in their original location after ten days service (joint 1-1) (test (g)) and later in joint location 3 (joint 3-1) after having been in this location one day for test (h) and four days for test (i). Joint 9-9 had regular 24-in. L-3 angle bars and was tested as found in the track (test (k)). Joint 11-11 (test (j)) was located on track 1, a track that was not in as good surface condition as the track on which all the other tests were made and apparently had not been surfaced since the previous spring. The tension of the bolts in this joint was low, an average of about 2000 lb. Joint bars of the symmetrical type were placed at joint locations 3 and 2 (joints 3-3 and 2-2, tests (l) and (m)) about five days before their tests were run. It has been noted that joint location 9 was about 60 ft. away from one end of the stretch of track that had been surfaced two months before in preparation for the tests; the lower bolt tension and other characteristics of the joint and the adjacent track indicated that no maintenance work had been applied to this joint and the adjacent track for several months except some relining and surfacing at uneven points in the track preparation made in July.

The first step in the reduction of data was to scale off the ordinate distance to the peak of the stress lines for each film for each instrument from a zero line considered to run between the straight lines at the two ends of the film record well away from the wheel load position. To facilitate the work cross-section paper was slipped under the film and the values read directly from the scale of the paper in hundredths of inches. The readings were later reduced to unit-stress by the use of the reduction factor that had been obtained from the calibration data for each instrument. The values of the stresses reported in this chapter are the actual indications of the instrument, whose effective point of measurement is located ¼ in. away from the surface of the bar. However, in calculating the corresponding moments this offset has been taken into consideration. The peaks of the film diagram were taken to represent the stress with the wheel directly over the instrument except in cases where the record clearly showed vibration along the line—the extent of this vibration was measured at points away from the peak. Readings were also made for the minimum position of the stress line between wheel loads (negative moment). For the instruments at sections 8 in. from the mid-section of the joint bars readings were taken at the peak, which corresponds to the wheel over the instru-

TABLE 7

### Designation and Conditions of Rail-Joints and Joint Bars—Tests on Pennsylvania Railroad at Claymont, Delaware

Twelve magnetic strain gages were used on the two bars of a rail-joint unless otherwise stated.

| Test Designation | Joint Number | Series            | Date of Test | Remarks                                                                                                                                                                                                  |
|------------------|--------------|-------------------|--------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| (a)              | 4-4          | 116-126           | 9-29         | L-3 38 1/2-in. bars. Joint undisturbed since July. Average tension in bolts, 29,000 lb.                                                                                                                  |
| (b)              | 4-4          | 127-137           | 9-30         | Same L-3 bars. Bolts loosened to about 2000 lb. tension. Thickness gages could be inserted at bar ends.                                                                                                  |
| (c)              | 4-4          | 170-178 & 181-182 | 10-2         | Same L-3 bars but sawed off to 24 in. Installed Oct. 1, 4:00 p. m. Average tension in bolts 28,000 lb.                                                                                                   |
| Special          | 4-4          | 179-180           | 10-2         | Same L-3 24-in. bars. Same bolt tension. Tie-plate over middle tie removed. Speed 5 m. p. h. only.                                                                                                       |
| (d)              | 4-5          | 229-238           | 10-4         | L-3 38 1/2-in. bars changed from joint location 5 Oct. 4, outer bar to outer bar position. 5 gages at mid-length of bars, 6 extensometer bolts. Average tension in bolts 14,000 lb.                      |
| (e)              | 4-5          | 248-259           | 10-6         | Same L-3 38 1/2-in. bars taken from joint location 5 on Oct. 4. Average tension in bolts 12,000 lb. Locomotive pulling 4 loaded cars.                                                                    |
| (f)              | 5-5          | 91-106            | 9-28         | L-3 38 1/2-in. bars. Joint undisturbed since July. The 3 joint tie-plates are found reversed. Test made as found. Average tension in bolts 14,000 lb.                                                    |
| (g)              | 1-1          | 138-149           | 9-30         | L-3 38 1/2-in. laterally deformed bars installed about Sept. 20. Average tension in bolts 12,000 lb. Only test at joint location 1.                                                                      |
| (h)              | 3-1          | 183-192           | 10-2         | L-3 38 1/2-in. laterally deformed bars taken from joint location 1 and installed in joint location 3 Oct. 2. Average tension in bolts 23,000 lb.                                                         |
| (i)              | 3-1          | 242-247           | 10-6         | L-3 38 1/2-in. laterally deformed bars taken from joint location 1 Oct. 2. 5 gages at mid-length of bars, 6 extensometer bolts. Average tension in bolts 13,000 lb.                                      |
| (j)              | 11-11        | 202-214           | 10-3         | No. 1 northbound track. L-3 38 1/2-in. bars. Joint undisturbed for several months. Average tension in bolts 2200 lb.                                                                                     |
| Special          | 11-11        | 215-218           | 10-3         | Same conditions as before except tie-plate over middle tie removed.                                                                                                                                      |
| (k)              | 9-9          | 107-115           | 9-29         | L-3 24-in. bars. Joint undisturbed for several months. Verona springs. Average tension in bolts 6200 lb.                                                                                                 |
| (l)              | 3-3          | 150-157           | 10-1         | 38 1/2-in. symmetrical bars installed Sept. 27. Average tension in bolts 14,000 lb.                                                                                                                      |
| (m)              | 2-2          | 158-169           | 10-1         | 38 1/2-in. symmetrical bars installed Sept. 27. Average tension in bolts 4000 lb. Only test at joint location 2.                                                                                         |
| (n)              | 4-5          | 239-241           | 10-4         | Same L-3 38 1/2-in. bars as in test (d). Tension in bolts entirely loosened, bars pinched out, then low tension (about 1000 lb.) set in all bolts. 5 gages at mid-section of bars, 6 extensometer bolts. |
| (o)              | 9-9          | 219-225           | 10-4         | Same L-3 24-in. bars. Bolts tight. No spring washers. 2 gages at top and bottom of outer bar, 4 P.R.R. extensometer bolts.                                                                               |
| (p)              | 9-9          | 226-228           | 10-4         | Same L-3 24-in. bars. Bolts loosened to about 5000 lb. Same set-up.                                                                                                                                      |
| Special          | 10-10        | 193-201           | 10-3         | Special 26-in. joint bars. Flat spring between bolts 2 to 3. Base plate. 9 gages on bars, 2 on base plate.                                                                                               |

ment. In some cases readings were also taken at points corresponding to the position of the wheel load at mid-length of the joint.

The general tests on the rail of the Pennsylvania Railroad with several locomotives at Claymont made in September and October 1930 were conducted by the staff of the Westinghouse Company before and after the tests on rail-joints. In these tests the stresses developed in the rail at different gage lines were measured with 8-in. magnetic strain gages under the moving loads of locomotive and cars. At one section of the track, two magnetic strain gages for each rail were placed on the two edges of the base of rail. At the same section a magnetic strain gage of suitable gage length was placed vertically on each rail, measuring changes in the vertical distance from a point on the outer surface of the head of the rail to a point on the upper surface of the outer flange of the rail. A magnetic strain gage was placed horizontally on the inner face of the web of the rail slightly above the geometrical axis. These vertical and horizontal strain gages were placed on both rails at the one section. Two other magnetic strain gages were placed horizontally on the inner face of the web of one rail at points 33 in. one way and 66 in. the other way from the section of track; two instruments were also placed at corresponding but not opposite positions on the other rail. The speeds used in the tests with the electric locomotive were 5, 45, 70 and 90 miles per hour, and in two runs 100 miles per hour. For the steam locomotives tests were made at 5, 45, 70, and 80 or 90 miles per hour. These are probably the highest speeds at which measurements of stresses developed in rail have ever been made. The records of these measurements of stress in rail were reduced by the Westinghouse Company and used for determining the running characteristics of the several electric locomotives at the various speeds and for making comparisons with the running characteristics of two types of steam locomotives of the Pennsylvania Railroad.

18. **Stresses in Joint Bars.**—In Fig. 40 is shown a film record of the magnetic strain gages at the two edges of the base of rail ( $\frac{1}{4}$  in. above bottom) as the electric locomotive moved past the instrument at a speed of 45 miles per hour. This diagram is reduced only slightly from the original film record. The vertical scale of each stress measurement is indicated. The zero line of stress has been drawn by connecting the two straight line portions of the far ends of the record; for the line drawn in the figure the measurements of stress are made to the upper edge of the width of the record, whether for tension or compression. The peak values of the record correspond to the stress immediately under a wheel and their ordinates give the tensile stress developed; the ordinates on the other side of the zero line give the compressive stress where negative moment is developed. Both stresses are measured from the same side of the record line. It may be noted that the vertical width of the line is nearly the same at all places so that the same results may be obtained by the use of either the upper or the lower side of the line. The mean stress under the two drivers was 14,400 lb. per sq. in. The shape of the diagram from left to right corresponds to the form of the curve of stresses found from analytical calculations, as is seen in Fig. 41.

In Fig. 42 is shown a film record of the magnetic strain gages at gage lines *A*, *B* and *C* at mid-section of the outer angle bar of joint 3-1 (test (i)) as the electric locomotive moved past the instrument at a speed of 45 miles per hour, together with a record of tension in bolt 4. The time taken by the locomotive in moving through the distance represented by the length of the record shown in Fig. 42 is 1.1 seconds, and the distance 73 ft. This diagram is about two-thirds the scale of the original film record. The zero line of stress has been drawn in the usual way by connecting the two straight

Fig. 40.—FILM RECORD OF STRESSES AT THE TWO EDGES OF BASE OF RAIL MEASURED BY THE MAGNETIC STRAIN GAGES—SPEED 45 MILES PER HOUR.

Fig. 41.—MAGNITUDE AND DISTRIBUTION OF ANALYTICAL STRESSES AND RAIL DEPRESSION FOR ELECTRIC LOCOMOTIVE 7850.

line portions of the record that are outside and away from the diagram shown in the figure; for the zero line drawn in the figure the measurements of stress are made to that edge of the width of the record into which the line merges. The peaks of the record correspond to a position of the wheels immediately over the instrument, and their ordinates multiplied by the scale for each instrument give the stress developed; the ordinates on the other side of the zero line give the stress where negative moment is developed.

Fig. 42.—FILM RECORD OF STRESSES AT GAGE LINES *A*, *B* AND *C* AT MID-SECTION OF THE OUTER ANGLE BAR OF JOINT 3—1 AS MEASURED BY THE MAGNETIC STRAIN GAGES—SPEED 45 MILES PER HOUR.

The vertical scale of stresses generally differs for the different individual records; in this diagram the scale is approximately the same for gage lines *A* and *B*, but that for *C* is considerably larger, as is seen by comparing the vertical scales equivalent to 10,000 lb. per sq. in. indicated in the figure. The ordinates from the zero line for the peaks for *A* and *B* indicate compression and those for the peaks for *C* tension. Between wheels the stresses change from compression to tension in *A* and *B* and from tension to compression in *C*. In each case all stresses are measured from the same zero line. The shape of the diagram from wheel to wheel and the general form of the stress curves for the joint bars are similar to those shown in the preceding figure for the rail, with the same kind of changes in stress from one wheel to another. The diagram in Fig. 42 is typical of the records found with all of the joints tested except, of course, for the rela-

tions of the magnitudes at the several gage lines and for the relative values of horizontal and vertical scales, and the form of the record is indicative of the flexural action at mid-section.

TABLE 8

**Observed Stresses at Mid-Section in L-3 Angle Bars for 130-lb. P.S. Rail—  
Tests on Pennsylvania Railroad at Claymont, Delaware with Electric  
Locomotive 7850**

The stresses in thousands of pounds per square inch are given for outer and inner bar. The average at the two drivers for the several runs at a given speed is reported. The letters *A*, *B* and *C* refer to the gage line for which the stress is recorded.

\*One run only.

†Two runs.

In Table 8 are given the observed stresses at gage lines *A*, *B* and *C* at mid-section of the angle bars, including the regular 38½-in. L-3 bars, those cut to 24 in. length, the laterally deformed bars, the 24-in. L-3 bars (joint 9-9) on track 4 away from the regular test track, and joint 11-11 on track 1. The values given are the averages for the two drivers and the several runs at a given speed. In Table 9 are given the similar average stresses in the symmetrical joint bars at gage lines *A*, *B* and *C* of mid-section, for which it should be remembered the coordinates differ from the general values for the

angle bars—especially for gage line *C*. In general, in all these tests, the average value given is for three or more runs at the given speed, except for the speed of 90 miles per hour and for a few cases where only one or two runs were made or where a record was questionable. It should be noted that the value 36,000 lb. per sq. in. for gage line *A* of the outer angle bar for joint 1-1 and a speed of 90 miles per hour represents only one run; it appears that the locomotive at this high speed gave values much more irregular than at lower speeds.

TABLE 9

**Observed Stresses at Mid-Section of Penn. Symmetrical Bars for 130-lb. P.S. Rail—Tests on Pennsylvania Railroad at Claymont, Delaware with Electric Locomotive 7850**

The stresses in thousands of pounds per square inch are given for outer and inner bar. The average at the two drivers for the several runs at a speed given in miles per hour is reported. The letters *A*, *B* and *C* refer to the gage lines for which the stress is recorded.

|              | C | 11.9 | 11.4 | 10.9 | 12.7  | 13.7 | 13.6 |

The compressive stresses in gage line *A*, which is near the highest point of the bars, are of course greater than those at the other gage lines and in several instances reach 25,000 lb. per sq. in. The stresses at gage line *B* are considerably smaller; this may be expected from its lower position and especially from the effect of the bearing pressure of the rail on the top fishing surface at and near the mid-section, as has been discussed heretofore. The effect of the bearing pressure is found to vary greatly with the different joints, and in some cases it varies considerably with the different speeds. The stresses at gage line *C* vary considerably depending upon the position taken by the neutral axis and probably also upon the lateral bending.

The stresses in the angle bars, measured at the several speeds, showed inclinations of the neutral axis similar to those found in laboratory and field tests under static loading. In the tests here reported the application of lateral bending moments due both to the condition of the rail support and to the way in which the wheel load was applied in a given run necessarily produced a variety of values of the inclination of the neutral axis, but the range in results was much the same as has been found with static loading.

The stresses in the bars at sections 8 in. away from mid-section, as measured from the records of the magnetic strain gages, agreed in general form and magnitude with the measured stresses with advancing wheel load found in the laboratory and previous field tests under static loading. The longitudinal scale of the records, however, makes it difficult to obtain accurate simultaneous values at the different sections when the load is at mid-section.

In making comparisons between joints or in determining the effect of speed, the magnitude of the stress at one gage line alone can not well be used because of the variability in the action of the different joints and variations in the application of load at different places and in different runs. Instead, the magnitude of the moment developed at a mid-section will be taken as the basis of comparison in the discussion of moments in joints in the following article.

**19. Moments in Rail-Joints.**—The variability in the action of joint bars by reason of differences in the inclination of the neutral axis and the effect of the bearing pressure of the head of the rail on the top fishing surface of the bar when load is applied make comparisons of rail-joints by means of measured stresses rather indefinite and unsatisfactory. Instead, the magnitudes of the moments developed in the joint bars as calculated from the measured stresses will be used. Reference is made at the end of Article 4 "The Function and Action of the Rail-Joint" to equation (67) and its use with two measured stresses considered as true flexural stresses, and in Article 11 "Distribution of Stresses over Vertical Section at and near Mid-Length" comparisons are made between the applied moment and the calculated moment in the laboratory tests of various rail-joints. It was shown that for a measured stress near the top point of the bar (say, gage line *A*, Penn. L-3, Fig. 3) and one on the lower part of the bar (say, gage line *C*) the calculated moment at mid-section does not differ greatly from the applied moment, but that when the upper gage line is at one side of the top point of the bar (say, gage line *B*) there is a considerable deficiency in the calculated moment. It was further shown that when the rail ends were moved apart so that the bearing of the head of the rails on the bars is well away from mid-length of the bars, the approximate value of the applied moment is given by calculations with the measured stresses at either of the upper gage lines, *A* or *B* and the stress at gage line *C*. The averages of the ratios in Tables 3, 4 and 5 are given as conversion ratios. When the moment obtained by equation (67) and the measured stresses at gage lines such as *B* and *C* is multiplied by the conversion ratio for the given rail-joint, the resulting value approximates closely to the applied moment for the conditions of the laboratory tests.

With the rail-joint in track the conditions may vary considerably from those of the laboratory tests. The bearing of the rail on the tie-plate or of tie-plate on tie may be eccentric and uneven and lateral bending and twisting may exist, both because of the eccentricity of support and of loading and because of the lateral forces applied by the wheel loads. For the outer bar the measured strains at gage lines *A* and *C* (or at other gage lines similarly situated with respect to the position of the bearing surface at the top of the bar at mid-length) will be assumed to be representative of the real flexural stresses at mid-section and no conversion ratio need be used for the field tests where great refinement is not warranted. For the inner bar where the strain at gage line *B* is the available measurement for the top portion of the bar, some method must be used to allow for the effect of bearing pressure upon the strain developed at gage line *B* at and near mid-section. The only information available in the field tests is the relation between the values given by gage line *A* and gage line *B* for the outer bar, and with the use of this relation must go the assumption that the inner bar acts in the same way as the outer bar or that their variation in action is in accordance with a lateral moment or other assumed difference.

After considering several methods of calculation, two methods of conversion for the moments of the inner bar at mid-section have been chosen—method *A*, the stress deficiency method, and method *B*, the method by use of lateral moments. In method *A*, the

bearing pressure of rail on bar upon application of load is considered to create a longitudinal tensile strain at gage line *B* which decreases the measurable compressive flexural stress in this gage line. From the data of gage lines *A*, *B* and *C* for the outer bar of any rail-joint and the assumption that gage lines *A* and *C* give the correct moment, the average stress deficiency of the stress at gage line *B* needed to give the correct moment by *B* and *C* is determined for the outer bar, generally for each speed used in the runs; this value of stress deficiency is then added to the observed value at *B* in the inner bar and the stress so found is used with the stress at *C* in the inner bar in making the calculations of moment in the inner bar at mid-section by means of equation (67). It will be seen that method *A* assumes that the effect of bearing pressure is the same in the inner bar as in the outer. The deficiency stress used will be expected to vary with different test loads.

In method *B*, the bearing loads are considered to affect the strain at gage line *B* at and near mid-section in a manner similar to an individual lateral bending of the bar itself, or at least that the value of the calculated lateral moment obtained from measured strains at *B* and *C* will be affected in magnitude proportionally to a lateral bending moment calculated from the measured strains at *B* and *C*. From the data of the outer bar, the moment ratio  $\frac{A\&C}{B\&C}$  (ratio of vertical moment obtained from gage line *A* and *C* to that obtained from *B* and *C*) is plotted as ordinate and the lateral bending moment by calculation from *B* and *C* by equation (68)\* as abscissa for each joint or type of joint and sometimes for each speed, and lines are drawn to represent the average trend of the plotted points. With the analytical lateral moment of the inner bar obtained from the stresses at gage line *B* and *C* (equation (68)), the diagram is then entered for the corresponding moment ratio  $\frac{A\&C}{B\&C}$ , and this value is used as the conversion ratio by which the values of the vertical moment obtained from gage line *B* and *C* by equation (67) is multiplied in obtaining the final value of the vertical moment for the inner bar.

Neither method *A* or method *B* takes into account the lateral bending of the rail-joint as a whole. In some respects method *A* seems to have rational characteristics, in others method *B* takes into account peculiarities of the action of a joint bar. The

\* Equation (68) for calculating the lateral bending moment developed in an unsymmetrical section of joint bar in terms of the measured stresses  $s_1$  and  $s_2$ , at any two points of a section,  $x_1, y_1$  and  $x_2, y_2$ , (the locations of which are chosen preferably at two points of high stress on opposite sides of the neutral axis, as for example gage lines *A* and *C* or *B* and *C* of the section of Penn. L-3 joint bars in Fig. 3) may be obtained by substituting in equation (44) the value of  $\tan \alpha$  given in equation (55), both to be found in the Fifth Progress Report. The equation is

$$M_y = \left( \frac{J_{xy}x_2 - I_y y_2}{y_1 x_2 - x_1 y_2} \right) s_1 + \left( \frac{I_y y_1 - J_{xy} x_1}{y_1 x_2 - x_1 y_2} \right) s_2 \quad \dots \quad (68)$$

where  $M_y$  is the lateral moment (resisting moment about a vertical gravity axis of the bar),  $x_1$  and  $y_1$  are the abscissa and the ordinate of the point in the section for gage line 1 taken with reference to the horizontal and vertical geometrical axes of the section, and  $x_2$  and  $y_2$  are similarly the coordinates for gage line 2, and  $s_1$  and  $s_2$  are the corresponding measured stresses, respectively, at the two gage lines.

moments obtained for the inner bar by either method do not appear to be far wrong. As before stated, the moment calculated from gage lines *A* and *C* approximates closely to the value of the moment developed in the outer bar. In the absence of information on the stress at gage line *A* in the inner bar, the vertical moment developed in the rail-joint at mid-section will be taken as the sum of the moment calculated for the outer bar from gage lines located like *A* and *C* without further reduction or conversion and the moment for the inner bar from gage lines *B* and *C* with the stresses or moments modified by the use of method A or method B, which takes into account properties of the same type of joint obtained from the stress data of the outer bar. Finally, the average of the values obtained by the two methods will be used in the comparison of the rail-joints.

It should be noted that it was shown in Article 11 "Distribution of Stresses over Vertical Section at and near Mid-Length" (see Table 3) that the observed stress at gage line *A* for mid-section is smaller than the real flexural stress and that the moments calculated from the observed stresses at gage line *A* and *C* in laboratory tests of angle bars taken from the track at Claymont average about 7 per cent smaller than the applied moments. As great refinement is not warranted in the reduction of the data of the field tests, the observed stress at *A* has been taken to be the real flexural stress. It is probable then that the moments hereinafter reported may be on the average 5 or even 10 per cent smaller than the actual moment, and because values at gage line *A* are involved in the conversion method this statement is applicable also to the moments in the inner bar.

It does not seem necessary to give the many details of methods A and B used in the reduction and conversion of the data of all the runs of the tests. A brief statement concerning the general values of the stress deficiency and the conversion ratio may be useful in judging of variations found. The following values approximate to the average value of the stress deficiency used in method A: tests (a) and (b), 6000; tests (c), (d), (e), 12,000 to 7000; test (f), 5000; tests (g), (h), (i), 11,000; test (j), 5000; test (k), 2000—all in pounds per square inch of stress which is added to the observed value of stress at gage line *B* of the inner bar before making the calculation of the moment in the inner bar. The following are the average values of the conversion ratios used in method B for multiplying the moments obtained from gage lines *B* and *C* of the inner bars to find the moment by this method, though the ratios used vary above and below these values according to values of the calculated lateral moments found in this inner bar: test (a), 1.20; (b), 1.45; (c) and (d), 2.20; (e), 1.50; (f), 1.40; (g), 1.40; (h) and (i), 1.80; (j), 1.35; and (k), 1.10.

In Table 10 are given the values of the moments developed in the outer and inner joint bars at mid-section under the first and second drivers by method A and method B for each run made at the several speeds for the Penn. L-3 rail-joints used in tests (a) to (k), and in Table 11 the values of the similar moments in the Penn. symmetrical bars by method A in tests (l) and (m). (See Table 7 for test conditions of the rail-joint.) For the lower speeds the variation between the several runs is not large. For higher speeds the variation is greater—in some cases considerably greater, due probably to the variability in the transfer of load from one driver to its companion on the same axle and to transfer from wheel to wheel on the same rail usual at such speeds, as the locomotive runs along the track. The data in Tables 10 and 11 show the variations from run to run at the various speeds. The information is useful in making detailed comparisons of the moments developed in the various rail-joints and their variations, especially at the higher speeds. The effect of speed will be discussed in Article 20.

TABLE 10

Vertical Bending Moments at Mid-Section in L-3 Angle Bars for 130-lb. P.S. Rail—Tests on Pennsylvania Railroad at Claymont, Delaware with Electric Locomotive 7850

Moments are given in thousands of inch-pounds for outer and inner bar and the sum. The grand average for each rail-joint does not include the results at 90 miles per hour. Values of moment for the inner bar were calculated by conversion methods A and B.

| Series and Speed                        | Method A     |       |     |               |       |     | Method B     |       |     |               |       |     |

In Table 12 are given in summary form the averages of the values at the two drivers and for all the runs at a given speed for the tests with L-3 joints; the corresponding averages for the Penn. symmetrical bars are given in Table 11. In discussing the values of these moments, one comparison that is useful is that made with the average moment developed in the full rail itself on this track with the given locomotive used in the tests. The calculated value of the moment in rail on the basis of  $u$  equal to 4000 and a weight on each driver of 37,500 lb. is 330,000 in.-lb. This value will be used as the base in making comparisons and in computing the joint moment ratio (ratio of the magnitude of moment in rail-joint developed by a given loading to the general value of the moment correspondingly developed in rail on the same stretch of track). The value of the moment in rail based on the stresses under the drivers obtained by the Westinghouse engineers at one section in each rail for one run at 5 miles per hour was 300,000

TABLE 11

Vertical Bending Moments at Mid-Section in Penn. Symmetrical Bars for 130-lb. P.S. Rail—Tests on Pennsylvania Railroad at Claymont, Delaware with Electric Locomotive 7850

Moments are given in thousands of inch-pounds for outer and inner bar and the sum. Values of moments for the inner bar were calculated by conversion method A.

| Series and Speed                    | First Driver |       |     | Second Driver |       |     | Average Moment in Two Bars for the Two Drivers |

in.-lb., but the calculated value named above is probably more nearly representative of the general value of the moment along the stretch of track. A tabulation of the joint moment ratios found in the tests is given in Table 13.

TABLE 12

**Summary of Vertical Moments at Mid-Section in L-3 Angle Bars for 130-lb. P.S. Rail—Tests on Pennsylvania Railroad at Claymont, Delaware with Electric Locomotive 7850—Average for the Two Drivers of All Runs at a Given Speed**

Moments are given in thousands of inch-pounds for outer and inner bar and the sum. Moments for the inner bar were taken as the means of the values obtained by conversion methods A and B.

\*Five runs at 18 miles per hour gave moments of 108,000, 125,000, and 233,000 in.-lb. in inner bar, outer bar, and two bars, respectively.

†With extensometer bolts.

††24-in. L-3 angle bars not on prepared stretch of track.

†††One run at 70 miles per hour.

In test (a) joint 4-4 (joint location 4 with bars found in joint 4, see Fig. 33), the condition of the rail-joint may be considered as normal for this stretch of test track—the bars were well fitting, the bolts were tight, the tie support apparently firm and having little play between rail and tie. The average value of the moment developed in two joint bars at mid-section for the runs at 5 miles per hour is 200,000 in.-lb.; this gives a joint moment ratio of .61. This ratio is within the range of the joint moment ratios found in tests of good track and reported in the Fifth Progress Report—perhaps somewhat below the average value for the best joints reported. In test (b) joint 4-4 (the same joint with bolt tension reduced to approximately 2000 lb.) the average moment developed in the joint bars at 5 miles per hour was 134,000 in.-lb. with a corresponding joint moment ratio of .41, a value 33 per cent less than that found with tight bolts. The lower bolt tension did not draw the bars into good contact with the rail for the full length of the bars and the thickness gages showed play between bar and rail head at and near the ends of the bars. The play between bar and rail evidently allowed the rail ends to deflect somewhat under the part of the application of load before the joint

TABLE 13

**Joint Moment Ratios at Mid-Section in Two L-3 Angle Bars for 130-lb. P.S. Rail—Tests on Pennsylvania Railroad at Claymont, Delaware with Electric Locomotive 7850—Average for the Two Drivers**

The speed is given in miles per hour. The base of the ratio is 330,000 in.-lb.

began to take moment proportional to the load applied. It should be noted, however, that the moments developed at speeds higher than 5 miles per hour approach those developed in test (a).

With the same bars sawed off to a length of 24 in. (test (c)) and bolts quite tight, the moment developed at mid-section was almost the same as in test (a), though the stress at the lower gage line was less, showing a difference in fit between bar and rail in the two cases and a change in restraint which would affect the action of an unsymmetrical bar. It is not to be expected that the moment developed in the shorter bars would be much different from that of the longer ones provided the fit of the bars was equally good. It is possible that subjection to traffic for a long period of time would develop differences not shown in this test.

The two tests with joint 4-5 (tests (d) and (e)) give values quite alike—the pulling of loaded cars would not be expected to change the magnitude of the moment developed—change of bolts from extensometer bolts to ordinary bolts without loosening the joint bars should not cause differences. The moment developed in the joint bars at 5 miles per hour was 219,000 and 229,000 in.-lb., corresponding to an average joint moment ratio of .68. The magnitude of the moment developed in joint bars 5 in their original position (test (f)) was approximately the same as that found with the same bars in joint location 4 (the joint moment ratio also being about the same)—evidently somewhat a matter of chance, for not only do two joint locations give differences in supporting conditions but the reversal of the tie-plates found in joint location 5 would be expected to produce abnormal conditions of bending.

In tests with joint bars 1 at joint location 1 and 3 (tests (g), (h), and (i)), the moments developed at mid-section of the bars designated as laterally deformed were greater than found in the tests previously mentioned. At 5 miles per hour the moments in the three tests are 286,000, 281,000 and 276,000 in.-lb., which correspond to joint moment ratios of .87, .85 and .84. The bars were unusually well fitting. The high value of the joint moment ratio seems not to be attributable to the form of the bars, unless the bearings of the deformed bars were such as to relieve the joint ties of part of their load. The bars had been in joint location 1 only ten days and in joint location 3 one and four days for tests (h) and (i), respectively, and the condition of the tie support for the recently installed bars may have been the source of the high values.

The low values of the moment in test (k) joint 9-9 with 24-in. L-3 angle bars, corresponding at 5 miles per hour to a joint ratio of .43, are not unusual in track that is considered good track in ordinary condition. Joint location 9 was away from one end of the stretch of track that had been prepared for the test work. At this place the rail and joint bar were two years old and had been subjected to heavy high-speed traffic, the ties at the joint were spaced further apart (22 and 25¾ in.) than those just beyond (20 and 19 in.), and surfacing had not been done recently. The measured tensions were 7000, 5000, 4000 and 21,000 in the four bolts. Play existed in one half of the length of the bars, as shown by thickness gages, but the high tension in one bolt held the other half well in place. The looseness of the tie-plate on the ties at or near one end of the rail-joint showed that these ties had been permanently depressed, but the joint would not be considered a low joint. It is well to note that the presence of low joint moment ratios represents undesirable conditions, which must lead to decreasing effectiveness in tie support and thus to injury to both rail ends and substructure.

The rail-joint on track 1 (the northbound passenger track; test (j) joint 11-11) was found to have low bolt tension (900, 1700, 1500, 3600, 5100 and 400 lb.). Thickness

gage measurements showed play between rail and bar. The rail and bars had been in track two years. The joint bars were  $38\frac{1}{2}$  in. long. The ties at the rail ends are spaced closer, 16 and 16 in., as compared with the spacing of 21 and 25 in. for the adjacent tie either way. The moment developed at mid-section of the bars at a speed of 5 miles per hour was 157,000 in.-lb. The corresponding joint moment ratio is .47. It should be added that neither joint 11-11 nor joint 9-9 was a "low joint", so far as was noticeable to the eye.

In test (l) joint 3-3 (Penn. symmetrical bars) the bolts had retained nearly full tension for the four days since installation. The moment developed under the drivers at 5 miles per hour (190,000 in.-lb., joint moment ratio of .58) is 68 per cent of that developed in the same joint location with the laterally deformed L-3 bars (tests (h) and (i)). The source of this difference is not apparent; though as joint 3-3 was fairly free from play the smaller stiffness of these symmetrical bars as compared with the L-3 bars would tend to decrease the moment developed at mid-section as compared with that developable in the L-3 bars under otherwise similar conditions. The joint moment ratios in tests (h) and (i) are, of course, unusually high.

The bolts of joint 2-2 (test (m), Penn. symmetrical bars) had lost most of their tension in the four days they had been installed. The moment developed under the drivers at 5 miles per hour (139,000 in.-lb.) corresponds to a joint moment ratio of .42. The low bolt tension and the relatively small moment of inertia in this joint and the conditions of the fit on the base of rail probably contributed to the lowness of the joint moment ratio, but the conditions of the tie supports may also have had a part.

The tests were made on joints having a variety of conditions with the view of finding something of their characteristics under moving load at various speeds and also to learn the effect of speed upon stresses and moments. The number of tests was not large enough to determine ranges in the values or even averages. For information of this kind reference may be made to the tests with static loading reported in the Fifth Progress Report of the Committee on Stresses in Railroad Track with 130-lb. and 127-lb. rail. In 20 consecutive joints on the Delaware, Lackawanna and Western Railroad on track that was not specially prepared for the tests and on which no work had been done for a considerable time the joint moment ratio ranged from .62 to .90 and averaged .75. In 7 joints on the New York Central Railroad on track in good condition but not specially prepared for the test yet having more unevenness from point to point the joint moment ratio ranged from .49 to .79 and averaged .62. These values and ranges may be considered as examples of what may exist on high grade track.

It should be added that the form of the curves of bending moment at mid-section of the joint bars when the locomotive passes by the instrument, as calculated from the observed stresses at top and bottom of bar, corresponds closely at all speeds to the curve of moments determined from analytical considerations. For the different speeds the ratio of the negative moment to the positive moment developed varies in the different joints, sometimes being greater than normal and sometimes less, depending principally upon the variation in rail support from tie to tie near the joint.

**20. Effect of Speed.**—For determining the effect of speed upon the stresses and moments developed in rail-joints, it is apparent that data from a considerable number of runs at each speed would be needed in drawing conclusions. For purposes of comparison there should also be data available for the stress in the rail opposite the joint taken simultaneously with the stresses in the joint and preferably also on the two rails at one or two places well away from the joint. Especially at the higher speeds, it is

known that a transfer of load occurs from wheel to wheel on the same axle and to a lesser extent from wheel to wheel longitudinally of the rail, as the locomotive moves along the track, and this change in wheel load complicates comparisons and increases the variability of results. The limitations of the test program did not permit this auxiliary information to be obtained. At 5 miles per hour, however, the stresses may be expected to correspond closely to the static loads of the wheels and their spacing. In the tests it was found that at the highest speeds the stresses in rail were quite variable, as shown by the data of the Westinghouse engineers, indicating considerable shifting of weight, and in the joint tests at 90 miles per hour and in some of those at 70 miles per hour the moment developed in the joint bars averaged even lower than at 5 and 45 miles per hour. The number of runs over a given joint in the tests at Claymont was not sufficient to give full information, and as nothing is known of the stresses in the rail opposite a joint the shifting of load from one end of an axle to another cannot be considered. The tests, however, do furnish information from which the trends of the effects of speed and important conclusions may be stated.

The values of the joint moment ratio (ratio of moment in two bars at mid-section to the general value of the moment in full rail elsewhere for static loading) are given in Table 13 for each run for the several joints from the moments recorded in Table 10, the tabulated value being the average for the two drivers by the methods A and B. These ratios will be used as a convenient basis of comparison. It is apparent that increases in moments in these joints due to speed are not large—quite in contrast to what has sometimes been thought to be the case. The average value of the ratios for the different speeds for the different tests is plotted in four groups in Fig. 43. The tests in each group are in some degree comparable.

Test (a) on joint 4-4 with high bolt tension (a well fitting joint) with very consistent data shows an increase from 5 miles per hour to 70 miles per hour of 7 per cent of the ratio at 5 miles per hour; the differences between extreme values for individual runs and the average value are generally not more than 10 per cent of the average value for that speed. In Fig. 43, it is seen that the increase in moment in test (a) is closely proportional to the changes in speed—7 per cent increase from 5 to 70 miles per hour. Test (b) on the same joint with low bolt tension shows an increase of 37 per cent from 5 to 70 miles per hour; the variation from run to run at 70 miles per hour is also quite small. Although this increase is much larger than in test (a), the joint moment ratio at 70 miles per hour still is less than for test (a), but it may be expected that the effect on the track substructure will be much greater than in test (a). Test (c) with the bars cut to a length of 24 in. gave an increase of 23 per cent for a speed of 70 miles per hour.

Tests (d), (e) and (f) are fairly comparable. The increase to 70 miles per hour in tests (d) and (f) averages 18 per cent; at 45 miles per hour the change is small. Here again the variation in the ratios for the several runs was small. Five runs in test (e) at 18 miles per hour gave values almost the same as at 5 and 45 miles per hour.

The group of tests (g), (h) and (i) gave similar joint moment ratios at 5 miles per hour (averaging about .85), which, as has already been noted, are considerably higher than those found in the other joints. At 45 miles per hour, slight decreases have occurred, but the three tests are closely grouped. In test (g) the ratio at 70 miles per hour is an increase of 7 per cent over that at 5 miles per hour. In test (h) at 70 miles per hour considerable variation is found and the joint moment ratio ranges from .70 to .94. In the one run of test (h) at 90 miles per hour the joint moment ratio was only

.65. In test (i) the one run at 70 miles per hour gave a ratio of only .70. These variations for the higher speeds may be attributed in part to transfers of load from wheel to wheel on the same axle for the runs recorded.

Tests (j) and (k) were made on joints that had lower bolt tension and that had been in track for some time so that the tie and ballast supports probably had been forced down to fit the changing condition in the fit of the joint. In the tests of both joints

Fig. 43.—JOINT MOMENT RATIOS DEVELOPED AT VARIOUS SPEEDS IN TESTS AT CLAYMONT, DELAWARE.

the joint moment ratio changed generally little with speed; in test (j) the ratios at the three speeds were .47, .48, and .45, and in test (k) .43, .52, and .42. In the latter test the value at 45 miles per hour is 21 per cent greater than that at 5 miles per hour. It seems probable that the smallness of values at 70 miles per hour is due to transfers of wheel load in the runs, as may also be expected to be the case for the low value of a run at 90 miles per hour.

It may be added that the highest value of the joint moment ratio obtained was 1.18 in the one run of test (g) at 90 miles per hour. Except for this value the joint moment ratio developed in the joints did not reach unity and thus never came up to the general value to be expected for the moment in full rail at 5 miles per hour. The general rate of increase to 70 miles per hour with tight bolts is less than 20 per cent, though in further runs greater transfers of load to the joint from the other rail might have been encountered. On the whole the increase in stress and moment in these joints with

speed for the locomotive used may be called small. It should be noted, of course, that this locomotive gave little or no counterbalance effect on the rail. It may be added that the rate of increase in moment in the joint bars noted in these tests is comparable with the rate of increase in moment in rail with increase in speed for tests with electric locomotives made on the Chicago, Milwaukee and St. Paul Railway reported in the Fourth Progress Report and smaller than most of the other speed effects reported for tests on rail with other locomotives and with cars.

**21. Bolt Tension in the Rail-Joints.**—Tension was measured in the regular  $1\frac{1}{8}$ -in. bolts of the rail-joint while in an unloaded condition by means of the caliper extensometer described in Article 6, and also by means of the Berry strain gage on the special extensometer bolts in a few tests. Changes in bolt tension under moving loads were measured with these special extensometer bolts and the magnetic strain gages, as will be described in the next article.

In Table 14 are given the tensions in thousands of pounds measured in the regular bolts in the unloaded rail-joints. Bolt 1 is at the north end of a joint, and for the 4-bolt bars the numbers 2 and 5 are omitted for test (k) and 1 and 6 for test (c). In tests (a) and (f) the bolts had probably not been wrenched up for two months and in (j) and (k) probably not for a longer time. In test (b) the bolts had been adjusted just before the test to the lesser tension noted; the second measurement gives the tension after the set of runs had been completed. For test (c) the sawed-off bars had been installed the day before the test was made with traffic running over the joint in the meantime; the tension was measured after the test runs were completed. For test (e) the bars from joint location 5 were installed at joint location 4 two days before the test was run and the tension was measured after the test runs were completed. For test (g) the bars had been installed ten days before and the bolt tension was measured directly after the test. For test (h) the installation and the test and the measurement were made on the same day. For tests (l) and (m) installation of bars was made five days before and measurement of tension made just after the test. The runs named in the column of Remarks correspond to series numbers in Table 7.

It is seen from the data of Table 14 that the tension existing in the bolts in the joints as found in the track was quite variable from joint to joint and from bolt to bolt. In test (a) (joint 4-4) the inner bolts had tensions of approximately 20,000 and 15,000 lb., the intermediate bolts 43,000 and 49,000 lb., and the end bolts 21,000 and 26,000 lb. The end and the inner bolts with tensions of 15,000 to 26,000 lb. may be termed "high"; the tension in the intermediate bolts is "extremely high", higher than the limits of useful tension indicated by the laboratory tests of the springing of the bars discussed in Article 10. In test (f) (joint 5-5) the tensions found, averaging 14,000 lb. and ranging between 9400 and 20,600 lb., are reasonably uniform and apparently sufficiently high. Only close observation would show that the bolts of joint 11-11 of track 1 (test (j)) had low tension. The end bolts had tension of less than 1000 lb. and the other bolts from 1500 to 5000 lb. The use of the thickness gage showed some vertical space between outer bar and rail toward the ends of the bar, but the inner bar seemed to fit fairly well. One rail end had been moving in the joint with temperature changes. Verona spring washers were found on joint 9-9 (test (k)). The bolt tension at one end of the bar was 7000 and 5000 lb. and at the other 4000 and 21,000 lb. It may be recalled that the joint moment ratios in tests (j) and (k) averaged about .46 at 5 miles per hour.

TABLE 14

## Bolt Tension in Rail-Joints of Pennsylvania Railroad at Claymont, Delaware

Measurements were made with caliper extensometer. Tension is given in thousands of pounds.

| Test Desig. | Jt. No. | Type of bars          | Bolt Number |      |      |      |      |      | Remarks                                                                                                    |

\*Measurement before making the runs of test (b).

†Measurement after making the runs of test (b).

In test (b) with the bolts unwrenched until the bolt tension measured just after the test averaged 2000 lb., the joint moment ratio fell to .41—test (a) gave .61 at 5 miles per hour under the same conditions except for bolt tension. Although the bars fit well in test (a), at the time of test (b) a thickness gage could be inserted at places along the bar and there was evidently vertical play between bar and rail. The lack of fit accompanying the low bolt tension permitted deflection of joint with correspondingly lessened stiffness of the joint and small moment-producing quality. Test (c) (bars sawed to 24 in.) with high tension in the four bolts gave about the same joint moment ratio as test (a). At the same joint location, the bars from joint location 5 and with a bolt tension moderate to high (tests (d) and (e)) gave a joint moment ratio of .68 at 5 miles per hour somewhat higher than the ratios found in tests (a) and (c) and about the same as that developed at the original location of these joint bars.

With the laterally deformed L-3 bars (tests (g), (h) and (i)) the tension was generally moderately high except that the inner bolts of joint 1-1 were lower and two of the bolts at one end of joint 3-1 were quite high. As was discussed in Article 19, the fit of this joint was excellent, but it is not apparent how much the high joint moment ratio (.85 at 5 miles per hour) was dependent upon fit or whether a camber or other unusual condition may have added to the moment developed.

The symmetrical type bars in test (l) fit well, though they apparently rested on the base of rail and not on the rail fillet as was intended in the design. The bolt tension averaged 16,000 lb., with one very high and one low bolt tension. The joint moment ratio developed was .58 as compared with .85 for tests (h) and (i) at the same joint location. For test (m) (joint 2-2) it is apparent that the bars had moved and readjusted their position with respect to the rail after the bolt tension was applied and before the time of the test so that the tension fell off greatly. The tension at the time of the test ranged from 200 to 8400 lb. The fit at the bottom was not good. These conditions apparently contributed to the lowness of the joint moment ratio, .42.

In Table 15 are given the tensions measured in the special extensometer bolts when installed in joints 4-5 and 3-1 both before and after certain test runs were made. The bolts were tightened to give approximately even tension in the six bolts. As was found in laboratory tests, during the first few loadings the tension fell off, owing to the opportunities for readjustment in the position of the bars with respect to the rail by reason of the differences in the flexure of the rail and the bar from point to point along the length. In test (d) the drop in tension ranges from 1500 to 7700 lb. and in test (i) from 5700 to 11,900 lb. There is indication that the loss in the end bolts is less than that in the others. The laboratory tests have shown that the loss of tension with additional loadings becomes smaller and smaller. Test (d) is directly comparable with test (e), and test (i) with test (h). The bolt tensions for each pair of tests are roughly comparable in their effects, and the joint moment ratios developed in each pair have correspondingly equal or similar values.

The use of the two measurements made at the two points beyond the two extreme elements of the special extensometer bolts furnishes information on the bending stresses put into the bolts by the tightening operation and brings out an indication of the unevenness and eccentricity of bearing that exists at both ends of the bolts and at the spring washers. In the bottom part of Table 15 are given the extreme fiber bending stresses in the horizontal plane (found by taking half the difference between the stresses at the two extreme fibers) for the twelve bolts in tests (d) and (i). The bolts had been wrenched up with unusual care and for most of the bolts the bending stresses are not large. The highest values of the stresses due to bendings are 11,000, 13,000 and 17,000 lb. per sq. in., which added to the average tensile stress in the bolt makes maximum fiber stresses of 35,000, 26,000 and 42,000 lb. per sq. in., respectively, in the three worst cases. It was noted that in these tests the bending stress in a bolt measured after a test is almost the same in amount as that measured initially, even though the tension in the bolt as a whole has dropped off materially. In some bolts the stress at one extreme fiber of the extensometer bolt was zero and that on the opposite fiber was double the average stress, which itself represents the effective tension in the bolt. The bending measured and reported was all in the horizontal plane through the axis of the bolt; bending in other planes would also exist, and that in the vertical plane will probably be greater than that in the horizontal plane. It should be borne in mind that these tests were made with accurately machined bolts and full finished nuts so that the eccentricity was

TABLE 15

**Tension and Bending Stresses in Bolts of Rail-Joints of Pennsylvania  
Railroad at Claymont, Delaware**

Measurements were made on the special extensometer bolts by means of a Berry strain gage. Bolt tension is given in thousands of pounds. The bending stresses at the extreme horizontal fibers of the bolts, reported in the lower part of the table, are given in thousands of pounds per square inch. Bars are L-3 38½-in. angle bars. Test (i) was made with laterally deformed bars.

due to the bearing on bars and spring washers and not to the bolts themselves. With the ordinary track bolt and ordinary wrenching the opportunities for the higher eccentricities and greater bending stresses would doubtless be increased. It should not be overlooked that the stresses at the threads are materially larger than those reported in the tables.

The Pennsylvania flat spring washers which were used in all the rail-joints except at joint location 9 closed down at a pressure of say 2000 lb. and gave little or no springing action at bolt tensions higher than this. The Verona spring washers used in the regular tests at joint location 9 had been flattened part way down, but the amount of elastic spring remaining in them was not measured. It was not apparent that the Pennsylvania standard spring washers had been instrumental in maintaining bolt tension in the joints as found in the track. In tests (o) and (p) at joint location 9, no washers were used with the special Pennsylvania extensometer bolts.

As before stated the data of the measured bolt tensions show marked variation and irregularity from bolt to bolt and joint to joint. The existing tensions varied from 200 to 49,000 lb. and in a single joint from 15,000 to 49,000 lb. and from 3000 to 33,000 lb.

It is obvious that it is extremely difficult to get an initial uniform tension in the four or six bolts of a joint, and the changes in position of the bar with respect to the rail made in the later adjustment under the bending effects of repeated loadings and unloadings will not be uniform for the several bolts, thus making variability in tension more marked after traffic has had its effect. The difficulty and uncertainty continue with later wrenching but in some respects the irregularities in the tensions become smaller. Regardless of the magnitude of the bolt tension this variability may not be troublesome if the tension is adequate for holding the bars in a position which ensures proper stiffness of joint and proper moment producing conditions, and these properties depend to a considerable degree on the shape and fit of the bars. It is very evident that the springing action of the bars under bolt tension aids in maintaining the tension in the bolts and thus in keeping the bars in proper position and contact with the rail.

**22. Changes in Bolt Tension under Moving Loads.**—The effect of moving loads upon the magnitude of the tension in the bolts of a rail-joint has long been a matter of interest and opinion and speculation—whether the tension increases or decreases under the passing load and especially whether it increases markedly at medium and high speeds. Information on the subject will have bearing on the action of the joint and on the function of the bolt, whether to hold the bars in proper contact and maintain the right fit or whether the forces acting during the passage of the load produce high tensions in the bolts that will have to be provided for. Static load tests (see Fifth Progress Report for results of laboratory tests) have shown certain increases and decreases in the tension upon application of load, with the magnitudes of the changes relatively small.

In order to determine the changes in tension in the joint bolts developed during the passage of the wheels of a locomotive or cars over a rail-joint at various speeds from low to high, the six special extensometer bolts heretofore referred to were designed so that the magnetic strain gages that were used in measuring stresses in the joint bars could be attached and used for giving autographic records of the tension in the individual bolts. The principle of the action of these special extensometer bolts is the same as for those described in Article 6 "The Laboratory Tests of Rail-Joints", but the form was adapted to the mounting of the magnetic strain gage used in the tests of joint bars, rather than a dial gage.

Fig. 44.—DIAGRAMMATIC REPRESENTATION OF SPECIAL EXTENSOMETER BOLT.

Fig. 44 is a diagrammatic representation of the special extensometer bolt. Fig. 45 shows a single extensometer bolt with the magnetic strain gage in place. Fig. 46 is a view of six extensometer bolts applied to a joint in the field tests. The body of the extensometer bolt is made of special alloy steel (3135 S.A.E. chrome nickel steel) heat-treated to give a high elastic limit and still retain sufficient toughness for shock resist-

Fig. 46.—VIEW OF SIX SPECIAL EXTENSOMETER BOLTS APPLIED TO A RAIL-JOINT IN TRACK.

ing qualities. A case-hardened full-finished nut was used. The bolt was made  $1\frac{1}{8}$ -in. diameter to conform to standard bolt size for the joints tested and was accurately machined to shape and size. A  $\frac{1}{4}$ -in. hole was drilled the length of the bolt on its longitudinal axis. At the thread end this  $\frac{1}{4}$ -in. hole was enlarged to  $\frac{1}{2}$  in. for  $\frac{3}{8}$  in. and threaded. The bottom of this hole was drilled out to  $\frac{3}{8}$ -in. diameter to fit the head of a  $\frac{3}{8}$ -in. actuating rod that extends the length of the bolt and screws and locks into the end of the magnetic strain gage which is attached to the movable armature. A closely fitting bushing supports the  $\frac{3}{8}$ -in. rod at the gage end of the bolt, permitting the rod to slide freely but limiting vibrations in the rod. This rod is fixed with reference to the threaded end of the bolt by screwing a safety set-screw into the  $\frac{1}{2}$ -in. hole mentioned above so that it bears on the head of the actuating rod. The shelf at the head end of the bolt is semi-circular in cross-section. At its far end a drilled and tapped hole in the supporting shelf takes the stud that carries the part of the magnetic strain gage that is attached to its coils and pole pieces. Thus any change in length of the bolt between the points of attachments of the actuating rod at one end and the far end of the magnetic strain gage causes a shortening of the air gap at one side and a lengthening at the other side of the armature. To give additional support and eliminate vibration a small screw is threaded through the bottom of the shelf and bears lightly against the gage.

For measuring the tension existing in the special extensometer bolts when the joint was not under a wheel load, an 8-in. Berry strain gage was applied between points *A* and *B* of Fig. 45. The gage point *A* is placed near the edge of the shelf at the head end of the bolt. At the threaded end of the extensometer bolt, the safety set-screw that fixes the actuating rod in place was made long enough so that a special washer may be put on and held with a lock nut (shown in the figures). The rim of this washer is cut to show a horizontal axial surface of sufficient area for the strain gage hole *B*. Two similar holes *A'* and *B'* are placed in the same horizontal axial plane as *AB*, one on the shelf and the other on the special washer. The two gage lines thus formed are opposite and equidistant from the longitudinal axis of the bolt. The averaging of the readings on these two gage lines will eliminate the effect of any eccentric loading of the bolt, and their differences will show eccentricity of bearing. This arrangement permits readings of changes in length under static conditions to be taken with an ordinary 8-in. Berry strain gage. The extensometer bolts were calibrated by applying known loads in a testing machine and noting the corresponding changes in the strain gage readings, as well as the movement of the actuating rod. A small key is held temporarily in a keyway common to the special washer and the threaded end of the extensometer bolt while the washer is locked into place, thus ensuring alignment of the horizontal surfaces on which the strain gage readings are taken. The use of the Berry strain gage in the manner described, in place of the magnetic strain gage, decreased the size of the air gap required (equivalent to increasing the sensitivity) and permitted the usual six records to be placed on one film.

The procedure of a test was to place the six special extensometer bolts in a joint with the magnetic strain gages in place but with the armature not yet fixed in position (locking screw loose) and apply a finger-tight tension. The actuating rod was screwed into the gage and locked and the safety set screw tightened, taking the precaution to see that this does not jam the gage which has about  $\frac{1}{8}$ -in. allowance for movement. The special washer was then locked into position as described above. A set of zero readings was taken with the Berry strain gage and the nuts tightened until the proper tension was obtained. The armatures of the magnetic strain gages were then locked in

a central position and the oscillograph adjusted to record the bolt tension changes under moving load. The amount of the total tension was again measured before loosening the nuts.

At the top of Fig. 42 is shown a film record of change in bolt tension for bolt 4 in test (i) at 45 miles per hour. In Fig. 47 and 48 are shown film records of the change in bolt tension in tests (i) and (o) at 45 miles per hour, together with a stress record at one gage line recorded for location purposes. The scale of the change in bolt tension is indicated for each individual bolt record.

Fig. 47.—FILM RECORDS SHOWING CHANGES IN BOLT TENSION AND A CONCURRENT RECORD OF STRESS AT A GAGE LINE—SPEED 45 MILES PER HOUR—TESTS AT CLAYMONT, DELAWARE—TEST (i) AT JOINT 3-1.

Use was also made of the extensometer bolts of the Pennsylvania Railroad to indicate the bolt tension changes at one joint location. Previous tests made with these bolts were reported and the bolts described in the Report of the Committee on Rail for 1930\*. In those tests telemeters of 2-in. gage length were used to indicate the changes of bolt tension. For the tests herein reported the bolts were adapted to the mounting

\* Vol. 31 of the Proceedings of the American Railway Engineering Association (1930), page 1556.

of the 4-in. magnetic strain gage. The mountings were rotated 90 degrees from the position previously used so that the magnetic strain gage was at the side of the bolt. The fit of the moving parts in their bearings was also improved.

Before considering the results of the tests it will be well to state that the changes in tension during the passage of a wheel over a rail-joint were found to be relatively small, frequently less than 500 lb., sometimes 1000 lb. or so, and in some cases 2000 or 3000 lb. At the same time the higher speeds were sometimes accompanied by vibrations of extensometer bolt or of its parts which made the record somewhat less distinct but which could generally be read with fair accuracy and which without doubt represented the

Fig. 48.—FILM RECORDS SHOWING CHANGES IN BOLT TENSION AND A CONCURRENT RECORD OF STRESS AT A GAGE LINE—SPEED 45 MILES PER HOUR—TESTS AT CLAYMONT, DELAWARE—TEST (o) AT JOINT 9-9.

tension changes. In a few cases vibrations on the record masked the changes in tension, though even here the full amount of the vibratory record would have given only a moderate change, in the worst cases less than 3000 lb. The interpretation of the tests was further complicated by the decreasing tensions from run to run when because of the bars moving toward the rail slightly under the action of the flexure of the bar and rail at each loading after a recent tightening, and by the increasing tensions when the bars moved outward slightly after a recent loosening of bolts without the bars being pried out. Sometimes the horizontal scale was so small that there was uncertainty as to whether the changes on the passage of a wheel were first plus and then minus or first minus and then plus or to what extent the increase and decrease was caused by vibration of rail or

bolt or extensometer. Time was not available before the tests were begun to make better adjustment between the magnetic strain gage and the extensometer bolt and to perfect the technique in a way that would have improved the quality of the records.

With these complications and the chances for instrumental error and the uncertainties in some of the records made, it seems desirable to give an interpretation of the results in a general way rather than to report a tabulation of quantitative results. It is believed that the results as a whole are definite and will serve the purpose of answering most of the questions raised with respect to the effect of speed upon the changes in tension in the bolts.

The tests on changes in bolt tension with the passage of a wheel over a rail-joint were conducted on three of the joints on which stresses in angle bars had been found. The tensions in the bolts with the joints in an unloaded condition were measured immediately before and after the runs for tests (d), (i) and (n) and are given in Table 15. The changes in bolt tension given in the following discussion refer to the increase and decrease in tension as the first driver and the second driver pass directly over the joint.

The records at 5 miles per hour were definite and certain. In joint 4-5 (test (d), tight bolts) the changes in bolt tension during the passage of the two drivers were small, 100 to 300 lb. as read from the record, generally an increase though bolt 4 gave decreases. At 45 miles per hour the increases in the end bolts were 1000 and 1500 lb. and in the others increases or decreases of 500 to 1000 lb. At 70 miles per hour the tension in bolt 1 increased by 1200 lb. and that in bolt 6 by 3000 lb., while that in the other bolts had plus or minus values ranging from 500 to 1000 lb. It is seen that with the increase in speed the magnitude of the changes has increased, but the higher values are not much greater than those found in the laboratory tests.

In test (n) (joint 4-5, with the tension in the bolts completely released, the bars pinched out, and then each bolt set with low tension, perhaps 2000 lb. or less—only one run at each speed), no changes in tension were noted at 5 miles per hour. At 45 miles per hour the increases or decreases in bolts 1 and 5 were about 1500 lb. and the changes in the other bolts were slight or the record was poor. At 70 miles per hour the increase in bolts 1 and 6 was about 1000 and 3000 lb. and in bolt 4 the decrease was about 3000 lb.—the other changes were small except that bolt 5 showed an increase of 3500 lb. under the first driver and no change under the second driver. It is apparent that the lessened restraint of the loosened tension has permitted a greater twisting of the bars.

In test (i) (joint 3-1 with high bolt tension) the changes in tension under the load at 5 miles per hour ranged from zero to 1000 lb. At 45 miles per hour (see Fig. 47 for four bolts of one run) the changes in tension were decreases of 500 to 1500 lb. in bolts 1, 2 and 5, and increases of about the same amount in bolts 3, 4 and 6. For the one run at 70 miles per hour the records that could be read with certainty were about the same, with bolt 5 showing a decrease of 2000 lb.

In test (o) (joint 9-9, with four Pennsylvania extensometer bolts screwed up quite tight, probably an average tension of 30,000 lb.), at 5 miles per hour the decreases in tension in bolts 1 and 6 were 500 lb. and in bolt 4 1000 lb., and no change in bolt 3. At 25 miles per hour the changes were slightly larger. At 45 miles per hour (see Fig. 48 for one run) the decreases in bolts 1 and 6 were 1000 lb. and in bolt 4 2000 lb. At 70 miles per hour the decreases in bolts 1, 4 and 6 were 2000, 2000 and 2500 lb. and the increase in bolt 3 was 1000 lb. It would appear that the bars were still being drawn in toward the rail during the tests.

In test (p), with the same joint 9-9 and the four Pennsylvania Railroad extensometer bolts loosened to a tension estimated at 5000 lb., the record showed little change in tension under load at 5 miles per hour. At 45 miles per hour the tension decreased 1000 and 500 lb. in end bolts and increased 2000 and 3000 lb. in inner bolts. These changes may have been due to a readjustment of the position of the bars with the rail under the reduced tension given by the flexure of the bars and rail upon the application of the loads.

Only small amounts of change in tension were found at the time the joint was between the first and second driver, unless of course the conditions were such that the first driver gave a permanent change in the tension of the bolt.

It may be concluded that the changes in bolt tension as each of the two drivers passes over the joint are not large even at a speed of 70 miles per hour. The change in bolt tension in the 6-bolt joints at 5 miles per hour was small, ranging from zero to perhaps 1000 lb. At 70 miles per hour, with tight bolts (tests (d) and (i)) the changes were about as follows: bolt 1, 2 and 3 1000 lb. or less, bolt 5 1000 and 2000 lb., and bolt 6 3000 lb. or less. With very low bolt tension (test (n)), the changes were somewhat greater. In the 4-bolt joint at 70 miles per hour the decreases were 2500 lb. or less, though probably much of this change was due to the bars working in toward the rail, the runs being made just after the bolts were tightened. In test (p) with lowered bolt tension, the change in end bolts was small and that in inner bolts at 45 miles per hour was an increase of 2000 or 3000 lb., both changes probably being due largely to the readjustment of bars with respect to rail with the lowered tension in the bolts. The sign of the change in tension, whether positive or negative, was generally similar to the signs found in the static tests, if the effect of recent tightening or loosening of bolts and the readjustment of bars and rail is taken into consideration. It may be added that the unsymmetrical form of the angle bars used may be expected to give greater changes in tension at loadings than would be found in bars of symmetrical section for the reason that the greater inclination of the neutral axis in the unsymmetrical section results in greater lateral deflection and a consequently greater lateral movement of the bars inwardly or outwardly, which acts to decrease or increase the bolt tension. The fit between bar and rail, however, must be accepted as having an important influence upon the changes in bolt tension developed under high speeds; the bars in the joints tested all had excellent fit.

The conclusions on the magnitude of the changes in bolt tension are quite contrary to some of the statements of an extreme increase in bolt tension during the passage of a wheel over the rail-joint given in Exhibit A of Appendix G of the Report of the Committee on Rail in Vol. 31 of the Proceedings of the Association. It should be added that the Pennsylvania extensometer bolts in general gave excellent records with the magnetic strain gages. It is evident, too, that the records made with the telemeter, given in the Report of the Committee on Rail just referred to, will give conclusions similar to those stated above if the large vibratory part of the record be recognized as due to vibration and only the tension effect be read.

#### IV. TESTS OF RAIL-JOINTS ON THE CHESAPEAKE AND OHIO RAILWAY

23. **The Tests of Rail-Joints on the Chesapeake and Ohio Railway.**—In March 1931 the Chesapeake and Ohio Railway in laying new 130-lb. R.E. rail on west-bound track one and a half miles west of Ashland, Kentucky, installed a number of rail-joints with 6-bolt 39-in. joint bars having a heavy section which approaches symmetry with respect to the horizontal geometrical axis. The section of the joint bars is the same as the section of the bars of symmetrical or near-symmetrical type used in the laboratory tests described in Chapter II "Laboratory Tests of Rail Joints" and referred to as the Santa Fe Symmetrical Type Rail-Joint. For convenience the joint bars will be designated as Santa Fe symmetrical bars. The section of the bars is shown in Fig. 3 and its geometrical properties are given in Table 2. The rail-joints were generally laid as supported joints. The track is described in Article 31 "Description of the Track".

This track installation furnished an opportunity to make field tests on rail-joints with heavy bars of a section that is nearly symmetrical with respect to the horizontal geometrical axis. The tests were conducted in September and October 1931. The stretch of track had been subjected to the extremely heavy traffic described in Article 31. Observations were made under static loading on 20 joints for the conditions found in the track to determine the stresses and moments at mid-section of the joint bars and at other sections under static loading. Determinations of deflection, vertical movement between rail and bars, and bolt tension were included in the program.

In the tests on the Pennsylvania Railroad heretofore described, the primary purpose was to determine the action of the rail and rail-joints under moving loads from low to high speeds and the magnetic strain gage gave excellent service, but the complication of the equipment limited the number of rail-joints available from a given position of the equipment and also limited the number and placing of gage lines for determining stress and other information. In the tests on the Chesapeake and Ohio Railway it was desired to make a study of a considerable number of joints in the condition found in the track and to obtain a variety of information on the stresses and deflections of the joints. For these reasons static loading was used and the measurements were made with Berry strain gages, deflection bars, and other instruments applicable to static loading conditions.

24. **The Tests.**—Steel hopper cars of 70 tons capacity were used in the tests. Three loads were used—(1) an unloaded car, (2) a car with a medium load, and (3) a car with a heavy load. Sand was used as a loading material, only the test end of the car being filled. The loads on the truck wheels of the test end of the cars were 26,000 lb. for the light load, 59,500 lb. for the medium load, and 119,800 lb. for the heavy load, which have been called 6500 lb. per wheel for the light load, 15,000 lb. for the medium load, and 30,000 lb. for the heavy load. It was noted that the bolster plates of the loaded end of the cars were always free so that the load on a given wheel may be expected to be fairly constant, and the assumption of equal division of load among the four wheels is not seriously in error, the possible error probably being nearly constant. In making a test on a rail-joint the car was spotted with the end wheel of the loaded end of the car at the desired position with respect to the joint.

The stress measurements were made with the 2-in. Berry strain gage, which has been referred to in Article 6 "The Laboratory Tests of Rail-Joints". A set of readings was taken before the load was placed in position, other sets with the load in place, and

generally a final set when the load had been removed. To compensate for temperature variations during the period of taking readings, a standard reference bar was used and when necessary suitable corrections were applied to the readings; its use also was a helpful warning in case of possible instrumental mishaps. Although the conditions in the field tests were not as favorable to accuracy as those prevailing in the laboratory, it is believed that with the skill used by the observer the errors of observation were not often greater than 600 lb. per sq. in.

Vertical movements between bar and rail were measured with a strain gage of suitable form and gage length. Deflections of rail-joint and rail were measured with a 66-in. bar described in Article 6. Vertical and lateral deflections of the joint bars were measured with a similar bar of correspondingly shorter length. Bolt tension was measured with the new caliper extensometer shown in Fig. 4.

For the more complete tests the time of taking readings on a rail-joint before loading, in loaded condition, and after unloading consumed from two to three hours. The routing of the trains over other tracks of the three-track railroad during most of the day enabled the test work to be carried on thoroughly and expeditiously.

The rail-joints along the stretch of track were numbered consecutively from 1 to 57, the odd numbers on the south rail and the even numbers on the north rail. Tests were made on 20 joints, 14 of them on the north rail and 6 on the south rail. The larger number of joints were chosen on the north rail (outside rail of outside track) because of convenience in the work and to keep away from the heavy traffic on track 2. With the exception of joint 28, which had the rail ends between two ties, the joints were supported joints and the rail ends came very close to the middle of the width of a tie.

Most of the rail-joints tested were taken consecutively along two stretches of track with a view of getting a knowledge of the general run of the joints along the track. Those on the south rail were chosen near certain of the joints on the north rail. The joints tested involved differing conditions—ties close against rail or loose, well fitting or fair fitting bars, bolts tight or loose, bars cocked out of vertical position, etc. Variations in conditions were made—bolts were tightened in some joints, and two pairs of bars were sawed to 26-in. length and re-installed in track.

The tests involved no repetitions of loading. Generally the end wheel of the loaded end of the car was placed directly over the rail ends (mid-section of joint bars). For the general tests the heavy load of 30,000 lb. on each wheel of the loaded end was used. The calculated moment for this load on full rail based on a modulus of elasticity of rail support of 2600 lb. per in. per in. is considered to be 260,000 in.-lb. and this will be used as the basis of comparison. In many of the tests the medium load of 15,000 lb. on each wheel was used and in a few the light load of 6,500 lb. The calculated moments for the medium and light loads are considered to be 130,000 and 56,000 in.-lb., respectively. The heavy wheel load is about 25 per cent higher than that of the capacity load of the 70-ton car—that is, a load somewhat greater than the allowable overweight load. The moment developed in the rail by this wheel load then corresponds fairly well with the moment developed under the front and rear drivers of the Mikado locomotives used by the railroad and is somewhat greater than that under the heaviest freight car load at slow speeds.

The stresses at mid-section were read at gage lines 1a, 2, 3 and 8 on the outer bar and 3 and 8 on the inner bar (see Fig. 3 for position of gage lines). For the six joints on the south rail the position of the wheel flange permitted readings of stresses in gage line 2 of the inner bar to be taken. The flange of a wheel was usually from 0 to  $\frac{1}{8}$  in. from the south rail and about  $\frac{3}{4}$  in. from the north rail. This evidently resulted

from a difference in the cant of the two rails, that of the south rail at points opposite the joints being generally about 1 in 16 and that of the north rail 1 in 27. It was noticed that similar positions were taken by flanges of wheels of freight trains which stopped along the track.

In addition to the readings at mid-section the stresses with heavy load were also read in seven joints at sections 2, 4, 6 and 12 in. each way from mid-section at gage lines 2 and 8 on the outer bar and sometimes at gage line 3, and at gage lines 2 and 8 on the inner bar where practicable and at 3 and 8 elsewhere.

With the medium and light loads, stresses were read at mid-section with load over mid-section only. These tests were made with a view of showing effect of the observed play in the joint and in the tie support on the development of stress and moment with the application of light, medium and heavy loads.

The heavy load was also placed 6 in. east or west of mid-section and in a few cases at 12, 18, 24 and 36 and 48 in. east of the mid-section. The stresses were read at mid-section. Ordinarily three gage lines were read on both inner and outer bar.

The vertical and lateral deflections of the two joint bars were read for most of the joints. The lateral bending was small. The deflection with the 66-in. bar was also taken at each joint, and the vertical movement between rail and bar at six places along the length of the bar. Thickness gage measurements were also made.

Notes on the general condition of the joints are given in Table 16. Bolt tensions were measured on the three joints in which changes of tension were made during the test. On all other joints an examination was made and the condition of the tightness or looseness of the bolt arrived at by judgment. The results of the tests and the examination of the bolt tension are given in Table 17. The bolts are numbered from west to east. In considering the tightness of the bolts, it should be borne in mind that the examination made might not detect a difference between a bolt tension of say 5000 lb. and a very high tension. Vertical movement between bar and rail on applying the load may indicate whether the bolt tension is low or high.

**25. Stresses and Moments in Joint Bars at Mid-Section and in Rail Opposite with Heavy Load over Mid-Section.**—Table 18 gives the values of the observed stresses at the various gage lines at mid-section of both joint bars with the end wheel of the heavy load directly over mid-section and also at the two edges of the base of the rail opposite the mid-section. For the outer bar the stress at gage line 1a near the highest point of the bar (see Fig. 3 for the position of the gage lines) probably approaches closely to the highest stress developed in the bar. The greatest stress measured was 28,200 lb. per sq. in. in joint 44. It will be noted that the stresses at gage line 1a differ widely from joint to joint, as they do also at the other gage lines. These differences indicate variations in the bending moments developed in the various joints by reason of the stiffness and variability of the rail supports and variable conditions in the joints themselves. There are also differences corresponding to differences in the lateral bending moments and in the amount and direction of the bearing pressure applied to the joint bars. Still another item that needs to be considered carefully is the effect of the bearing pressure of rail on bar at and near mid-section in modifying the relative magnitude of the stresses developed at the gage lines at the upper part of the bars.

In Article 11 "Distribution of Stresses over Vertical Section at and near mid-Length", the effect of the application of the bearing pressure on the top fishing surface of the bar near mid-section has been discussed. It was shown that the observed stress

TABLE 16

Notes on Rail-Joints—Tests on Chesapeake and Ohio Railway at  
Ashland, Kentucky

Unless otherwise noted, the joint was tested in its original condition with the heavy load only over mid-section and 6 in. east. H, M, and L refer to heavy, medium and light loading.

| Joint Number | Series  | Date     | Remarks                                                                                                                                                                                                                                                              |
|--------------|---------|----------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 14           | 88-90   | Oct. 3   | Low tension in east two bolts.                                                                                                                                                                                                                                       |
| 16           | 59-61   | Oct. 6   |                                                                                                                                                                                                                                                                      |
| 18           | 56-58   | Oct. 1   |                                                                                                                                                                                                                                                                      |
| 20           | 53-55   | Oct. 1   |                                                                                                                                                                                                                                                                      |
| 22           | 42-52   | Oct. 1   | Bolt tension measured. H applied at several positions. M at mid-section only.                                                                                                                                                                                        |
| 22           | 80-87   | Oct. 3   | Bolts tightened to measured tension shortly before test.                                                                                                                                                                                                             |
| 24           | 35-41   | Sept. 30 | H, M and L applied.                                                                                                                                                                                                                                                  |
| 26           | 130-137 | Oct. 9   | H and M applied.                                                                                                                                                                                                                                                     |
| 27           | 138-143 | Oct. 9   | Four bolts loose. H and M applied.                                                                                                                                                                                                                                   |
| 28           | 144-149 | Oct. 10  | Suspended joint. Every bolt loose. Inner bar is in at top and out at bottom. West rail has been slipping with change in temperature. The two joint ties are 12- and 10-in. widths, and the one first east is 14-in. Tie spacing large and variable. H and M applied. |
| 28           | 237-239 | Oct. 14  | Before test nuts were wrenched up about $1\frac{1}{2}$ turns to about 15,000 lb.                                                                                                                                                                                     |
| 41           | 99-104  | Oct. 8   | Three bolts loose—two low tension. H and M applied.                                                                                                                                                                                                                  |
| 42           | 1-6     | Sept. 28 | H and M applied.                                                                                                                                                                                                                                                     |
| 43           | 105-108 | Oct. 8   | Outer bar slightly out at bottom. H and M applied.                                                                                                                                                                                                                   |
| 44           | 14-20   | Sept. 29 | Bolt tension measured—mostly low. West rail has slipped in bars. Inner bar out at bottom and bearing on inner part of fishing surface. H, M and L applied.                                                                                                           |
| 44           | 62-67   | Oct. 2   | Bars sawed to 26 in. and installed with low bolt tension the day before test. Inner bar is slightly out at bottom. Fit and bearing are much the same as in series 14-20.                                                                                             |
| 44           | 68-70   | Oct. 2   | Four bolts in 26-in. bars tightened to 10,000 lb. Inner bar only slightly out at bottom.                                                                                                                                                                             |
| 45           | 109-110 | Oct. 8   |                                                                                                                                                                                                                                                                      |
| 46           | 7-13    | Sept. 28 | Bolt tension measured. H, M and L applied.                                                                                                                                                                                                                           |
| 46           | 91-95   | Oct. 3   | Bolts tightened to 11,000 lb.                                                                                                                                                                                                                                        |
| 47           | 21-27   | Sept. 29 | H, M and L applied.                                                                                                                                                                                                                                                  |
| 47           | 223-225 | Oct. 13  | Bars sawed to 26 in. and installed with low bolt tension four hours before test. The low tension was not sufficient to draw the bars properly into place. Outer bar is slightly out at bottom.                                                                       |
| 47           | 229-230 | Oct. 14  | Bars tightened to 15,000 lb. or more and several trains ran over track. Bars had been pulled into proper place and fit well.                                                                                                                                         |
| 48           | 28-34   | Sept. 30 | H, M and L applied.                                                                                                                                                                                                                                                  |
| 48           | 226-228 | Oct. 13  | Bars taken off and reapplied with low bolt tension the day before test. Tension not enough to draw the bars into proper place.                                                                                                                                       |
| 48           | 231-234 | Oct. 14  | Bolts tightened to 15,000 lb. or more so that bars fit fairly well. Several trains over before test.                                                                                                                                                                 |
| 50           | 111-117 | Oct. 9   | Inner bar in at top and out at bottom and bearing well toward inside at bottom. H and M applied.                                                                                                                                                                     |
| 56           | 118-123 | Oct. 9   | Generally low bolt tension. H and M applied.                                                                                                                                                                                                                         |
| 57           | 124-129 | Oct. 9   | Tension not more than 1000 lb. except bolt 2. Bars loose.                                                                                                                                                                                                            |
| 57           | 235-236 | Oct. 14  | Nuts wrenched up $1\frac{1}{2}$ turns making 15,000 lb. tension or more. H and M applied.                                                                                                                                                                            |

TABLE 17

### Condition of Bolt Tension in Rail-Joints of Chesapeake and Ohio Railway at Ashland, Kentucky

Unless otherwise stated the description applies to tests made with the original bolt tension found in the joint. L, loose—probably not over 1000 lb. tension; LT, low tension—probably under 5000 lb. tension; T, tight—probably 5000 lb. or above. Measured tension is given in thousands of pounds.

| Joint Number | Series  | Bolt Number |      |      |      |      |      | Remarks                                                                                                         |
|--------------|---------|-------------|------|------|------|------|------|-----------------------------------------------------------------------------------------------------------------|
|              |         | 6           | 5    | 4    | 3    | 2    | 1    |                                                                                                                 |
| 14           | 88-90   | LT          | T    | L    | T    | T    | T    |                                                                                                                 |

|              | 229-230 |             | T    | T    | T    | T    |      | High bolt tension applied.                                                                                      |
| 48           | 28-34   |             |      |      |      |      |      |                                                                                                                 |
|              | 226-228 |             |      |      |      |      |      | Bars taken off and reapplied the day before the test. New tension not high enough to draw bars into proper fit. |
|              | 231-234 | T           | T    | T    | T    | T    | T    | High bolt tension applied.                                                                                      |
| 50           | 111-117 | L           | T    | T    | T    | T    | T    |                                                                                                                 |
| 56           | 118-123 | T           | LT   | LT   | LT   | LT   | LT   |                                                                                                                 |
| 57           | 124-129 | L           | L    | L    | L    | LT   | L    | Bars very loose—tension not much more than 1000 lb. except No. 2 may have had 5000 lb.                          |
|              | 235-236 | T           | T    | T    | T    | T    | T    | Nuts wrenching up about 1½ turns—tightened to a high tension.                                                   |

at gage line 1a (a point close to the upper fishing surface) is considerably greater than the calculated bending or flexural stress necessary to produce a given applied moment, and that the observed stress at gage line 2 (a point well out toward the outside edge of the head of the bar) is somewhat less than the calculated bending stress at this point for the given applied moment, and also that the observed stress at gage line 3 (a point on the side of the head) is considerably less than the calculated bending stress at this point. In the laboratory tests with new 26-in. Santa Fe symmetrical bars, where the loads were applied vertically and without some of the variable conditions found in the track (see Table 5), the average ratios between the moments calculated from the observed stresses at gage lines 1a, 2, and 3 (each in combination with gage line 8) for two pairs of bars and the applied moment were about 1.25, .93, and .83, respectively. For these laboratory tests, then, to obtain the applied load from the observed stresses

TABLE 18

Observed Stresses at Mid-Section of Santa Fe Symmetrical Bars and at Base of Rail Opposite with Heavy Load over Mid-Section—130-lb. R.E. Rail—Tests on Chesapeake and Ohio Railway at Ashland, Kentucky

The stresses are given in thousands of pounds per square inch for a load of 30,000 lb. on each wheel of a four-wheel truck.

| Joint Number | Series | Outer Bar |      |      |      | Inner Bar |      |      | Base of Rail |       |
|--------------|--------|-----------|------|------|------|-----------|------|------|--------------|-------|
|              |        | 1a        | 2    | 3    | 8    | 2         | 3    | 8    | Outer        | Inner |

the moments calculated from the observed stresses would have to be multiplied by the conversion ratios, .80, 1.07 and 1.20.

With the conditions of loading and of the tie supports at the joints in the track, lateral bending of bars and of the joint as a whole occurs as well as vertical bending. On the assumption that the observed stresses represent the actual flexural stresses, equation (67) (see Article 4) may be used to calculate the vertical bending moment developed in a bar and equation (68) (see article 19) the lateral bending moment developed in the bar for both unsymmetrical and symmetrical sections. In calculating vertical moments, if allowances have to be made for excess or deficiency in observed stresses because of the effects of bearing pressures near mid-section special modifications in the calculations will need to be made in some way.

From the data of the laboratory tests on the Santa Fe symmetrical bars, as noted above, the vertical moments calculated from the observed stresses at gage lines 1a and 8 and 2 and 8 would have to be multiplied by conversion ratios of .80 and 1.07, respectively. Naturally the conversion ratios for joints in track may be expected to differ considerably by reason of difference in fit and tightness and condition of rail support. The ratios between the vertical moments calculated from stresses at 1a and

8 and those calculated from 2 and 8 varied rather widely for the joints tested in track. The average of these ratios for the track was about 1.20, while the corresponding average ratio for the laboratory tests was 1.35. It would appear that the values of the stresses at gage line 2 are relatively more closely representative of the moments than those at gage line 1a, since the stresses at 1a are likely to be affected more largely by the variations in the magnitude and position or the distribution of the bearing pressures than are those at gage line 2. The values of the stresses at gage line 2 when available have therefore been used in the calculation of the vertical moments. It has not been thought best to make an allowance for a deficiency in moment when calculating from gage lines 2 and 8 such as was found from the laboratory tests. Instead, the values of the moments calculated from the stresses at these two gage lines, when available, will be used as the moments developed at mid-section. The variation in the data of the various joints and the differences in the condition of the joints and their supports make it seem well not to go into refinements that may not be justified. At the same time the view may be expressed that the moments developed in these joints, considering the results of the laboratory tests, are on the average probably 5 or even 10 per cent greater than the values calculated from gage lines 2 and 8.

The foregoing discussion refers to the outer bar and to the calculations for the inner bars where gage line 2 was usable. For the inner bars not having readings on gage line 2, a method of conversion ratios for the moments calculated from gage lines 3 and 8 must be provided to overcome the large deficiency in stress at gage line 3. For this symmetrical section the conversion ratio by which the moment in a bar calculated from the observed stresses at gage lines 3 and 8 is to be multiplied will be based on the ratio of the lateral moment calculated from the observed stresses in gage lines 3 and 8 to the vertical moment calculated from the same stresses,  $\frac{M_y}{M_x}$ . It was found that for the outer bar the ratio  $\frac{M_y}{M_x}$  calculated from the stresses observed at gage lines 3 and 8 when plotted against the ratio of the vertical moment calculated from gage lines 2 and 8 and that from 3 and 8  $\frac{M_{2 \text{ and } 8}}{M_{3 \text{ and } 8}}$  with a very few exceptions gave points close to a straight line. This means that the deficiency in the vertical moment by the use of gage line 3 affects the calculated moment in a way similar to the effect on the lateral moment. The lateral moment was calculated by equation (68) (see Article 19). The conversion ratio for use with the inner bar was then taken from a diagram prepared from the data of the outer bar; the vertical moment calculated from gage lines 3 and 8 was multiplied by this conversion ratio and considered the moment developed in the inner bar. It should be stated that the observations indicate that the lateral bending stresses and moments referred to are largely local manifestations, not extending far from the point of application of bearing pressure on the top of bar and that the conversion method used is dependent on an analytical consideration of the local conditions at and near mid-section. Doubtless there are cases where the method has not given a correct result, as was found in a few cases on the outer bar, but on the whole it may be expected that the results are fairly close to the actual moments. It may be noted that the magnitudes of these moments are subject to the same general comment as those of the outer bar—their average is probably low by 5 per cent or more.

In Table 19 are given the vertical moment in joint bars at mid-section with end wheel of the heavy load over mid-section calculated from the observed stresses by the methods just described and also the moment in the rail opposite mid-section. The

joint moment ratio (ratio of moment in joint to the general value of the moment in full rail at places away from the rail-joint, the value of this base being taken as 260,000 in.-lb.) is also given in the table. The rail moment ratio given for the rail opposite a joint is based on the same general value of the general moment in the rail. The joint moment ratios are convenient for making comparisons of moments. It will be seen that the joint moment ratio for the several joints is quite variable, ranging from .40 to .96 for the joints in their original condition.

TABLE 19

Vertical Bending Moments at Mid-Section of Santa Fe Symmetrical Bars and in Rail Opposite with Heavy Load over Mid-Section—Tests on Chesapeake and Ohio Railway at Ashland, Kentucky

Moments are given in thousands of inch-pounds for outer and inner bar and the sum. The base of the moment ratios is 260,000 in.-lb.

| Joint Number | Series | Moment in Bars |           |     | Joint Moment Ratio | Moment in Rail Opposite | Rail Moment Ratio | J.M.R.<br>R.M.R. |
|--------------|--------|----------------|-----------|-----|--------------------|-------------------------|-------------------|------------------|

\*Moment from gage lines 2 and 8 of Inner Bar.

Several sources for the variation in the magnitude of the moment developed in a joint may be noted—spacing of the joint ties as compared with that away from the joint, the fit of the bars to the rail and the play between rail and bars at points along the length of the joint, tension in the bolts, deflection of the joint and adjacent rail, and condition of rail support relative to play between rail and ballast bed from point to point and to stiffness of the support when good bearing has been reached.

For the stretch of track on which tests were made, the spacing of the three joint ties was usually somewhat smaller than that of the ties adjoining and was in most cases fairly uniform, although variation in the width of tie and the spacing probably contributed somewhat to the variations in the moments. The fit of bars and rail and the play between rail and bar was generally satisfactory except in a few joints when the bolt tension had not drawn the bars into place. It was found that except for loose bolts and very low bolt tension these joint bars gave small play and reasonable deflections even without very high tension in the bolts. The variation in the position of the tie and the ballast bed with reference to the rail for adjacent ties and groups of ties (that is, the vertical play between rail and ballast bed) was very marked and evidently was the principal source of the variations in the action of the joints. In Chapter V "Track Depression and Rail Stresses in Tests on the Chesapeake and Ohio Railway", the wide variation in stresses in rail in this track is discussed and the great variability is traced to the variability in the conditions of rail support and the great range in play between rail and ballast bed from point to point along the track. The same variability in rail support exists at and near the joints and will be found to be the principal contributor to the variability in the moments developed in the joints.

Information on bolt tension, play of bars, deflection, and condition of support is not always available. Comments on the results in tests of joints in their original condition on which conditions were not changed in later tests will first be made. Reference may be made to Tables 16, 17, 18 and 19.

Joints 14 and 20 may be considered to have ordinary conditions and normal moments for the condition of the track tested. The low bolt tension in joint 16 may have contributed to the small value of the moment and the joint moment ratio. The depression or "hole" at two joint ties of joint 18 (meaning the large vertical play between rail and ballast bed) may have increased the moment in the bars. The abnormally large moment in joint 22 (joint moment ratio .91) evidently was caused by the "hole" at several ties (see Fig. 64 for play between rail and ballast bed). The deflection in 66 in. was large. In joint 24 the firmer support at two joint ties and their closer spacing, as compared with the support on either side, were the principal sources of the small moment, regardless of the fact that the fit of the bars was excellent. The vertical movement between bar and rail was above average, resulting in more than average deflection in 66 in. for the moment developed, but otherwise the action would be called ordinary. Joint 27 (joint moment ratio .67) had several loose bolts and the deflection in 66 in. was 31 per cent greater than the value proportional to the moment in the joint, as given by the line in Fig. 55.

In joint 41, with three bolts loose and a vertical movement between bar and rail greater than normal and the support of the three joint ties firmer than the adjoining ties each way, the conditions would be favorable to a lower joint moment ratio than is recorded. In joint 42 the conditions of the rail support would tend to make the moment small. The three loose bolts apparently did not affect the fit of the bars except that there was vertical movement between rail and bar of .007 and .009 in. at the rail ends and the deflection in 66 in. was 10 per cent over the average deflection for the moment developed. In joint 43 the two loose bolts at one end had little effect on fit and vertical movement of bars. The support of the joint ties in relation to that of the ties on the east would tend to keep the moment low. The deflection was normal. In joint 45 with tight bolts, the joint ties were on the sloping east side of a deep "hole" (see Fig. 65), and the other truck wheel was in another hole further east, conditions which doubtless were sources for the very low joint moment ratio, .40; the rail moment ratio in

the rail opposite this joint, in a similar situation with respect to the adjacent depression in the support was only .61. Joint 50 had tight bolts and well fitting bars. The deflection in 66 in. was normally proportional to the moment developed in the joint. Although information is not available on the condition of the tie supports, it is probable that variation in support at and near the joint is the source of the low moment. Joint 56, with low bolt tension, had its joint ties situated on the edge of the sloping east side of a very deep "hole" at the west of the joint and the tie supports at the east supporting the other truck wheel were higher, so that it may be concluded that the abnormal supporting conditions were the source of the high moment. In joint 57, loose bolts and large vertical movement of bars with respect to rail together with firmer supports at two of the joint ties combined to produce a very low joint moment ratio.

The effect of change of the bolt tension from a low to a higher amount may be expected to depend upon several circumstances. If the tension is low or the bars loose and this condition has existed for some time, an increase in tension will probably decrease the play or vertical movement between bar and better the fit and thus decrease the deflection in the rail-joint as a whole. Whether this change will result in an increase in the moment developed will depend upon the relative conditions of the tie support at and away from the joint. If the conditions of the tie supports with respect to play and stiffness of support are fairly uniform, the tightening of the bolts from a loose condition may be expected to increase the moment. If the condition of the supports at the joint ties govern, there may be little change in moment. For bars of symmetrical section, a low bolt tension which holds the bars well in position may not be expected to produce much immediate change in the moment developed. Some of these comments are illustrated in joints tested with both original and increased bolt tension.

In a few joints the bolts were tightened before a second test was made. In joint 22 the original bolt tension ranged from 1700 to 10,400 lb., altogether not a very low bolt tension for the symmetrical form of bar and not one that should give low moments. When the bolt tension was increased to about 20,000 lb. the sum of the vertical movements between bar and rail remained nearly the same, but the deflection in 66 in. decreased in the same proportion as the joint moment ratio, which changed from .91 to .84. The original bolt tension in joint 46 ranged from 1700 to 6200 lb., a low tension, but the bars were held in place. Tightening the bolts to 10,000 lb. reduced both vertical movement and deflection very slightly and the moment increased only slightly. This joint was at the edge of a deep "hole". In joint 57 the bars were quite loose and the bolts did not appear to have more than 1000 lb. tension except bolt 2 which may have had 5000 lb. The position of the bars was readily moved with a hammer. The rail-joint received considerable support at the joint ties. Wrenching the nuts to a high tension had the effect of increasing the joint moment ratio from .42 to .66.

After the test of joint 48 in its original condition, the bars were taken off and again put on a day before the tests of series 226-228 and 231-234 were made. The bars were purposely applied in a careless way and the bolts given a low tension, which did not draw the bars up to the original place. The joint moment ratio was reduced from .70 in the original condition to .47. Upon applying a tension high enough to draw the bars into proper fit the joint moment ratio was found to be again .70.

In two joints the bars were sawed off to 26 in. and placed back in track with four bolts having about the same low tension in each bolt as the bolts in the 39-in. bars had originally, and after a test the bolts were tightened to a higher tension and the joint again tested. In both cases, the pull-up and push-down tests show that the middle joint tie gave inadequate support. In the original condition of joint 44, for some unknown

cause an extremely high moment was developed (joint moment ratio .96). In series 63 and 66 with low bolt tension and bars not drawn closely into position and tested first with the end wheel over the joint and then with the other wheel of the truck over it, the joint moment ratio for the 26-in. joint fell to .85. When the bolt tension was tightened to about 10,000 lb. the resulting joint moment ratio was .62. In this connection it may be noted that the observed vertical deflection in the bars for 25 in. was smaller for the last test than for the others. For the original condition of joint 47 (with bolt tension not observed, but with vertical movement between rail and bar extremely small) the joint moment ratio was .47. When the 26-in. joint was tested with low bolt tension, not high enough to have drawn the bars in to proper position, the joint moment ratio was very low, .28. Upon applying a high tension in the bolts and overcoming the play of the bars, the joint moment ratio rose to .60. These few tests are so limited and the conditions are so unrepresentative that the results should not be used in comparing the action of long and short bars.

In joint 28, the rail ends came between ties (suspended joint) at the side of a "hole", all bolts were loose, and the vertical play of the bars was considerable. The high value of the joint moment ratio (.94) corresponds to the large value of the deflection in 66 in. When the bolts were given a high tension the joint moment ratio became .85. The conditions of this joint were abnormal.

In Table 19 are also given the values of the moments developed in the rail at a point directly opposite a rail-joint. These magnitudes vary greatly from point to point; the variation in moments and in play between rail and ballast bed are discussed in the next chapter. The moment opposite joint 50 (384,000 in.-lb.) is extremely high. In the column marked "Rail Moment Ratio" the ratio of the moment developed in the rail at the section opposite a rail-joint to the general value of the moment developed in the rail by the heavy load (taken as 260,000 in.-lb.) is given. In the last column (marked

$\frac{J.M.R.}{R.M.R.}$ )

the quotient of the joint moment ratio divided by the rail moment ratio is given. The average of these quotients or ratios is about .75. With a few exceptions, which are generally explainable by the conditions of the joints and the rail support, the ratios are reasonably concordant. The ratio .75 may be taken to represent the moment developed in the rail-joint in terms of that in the rail opposite it.

It may be concluded that the principal source of the variability in the magnitude of the moment developed in the joint bars and the consequent joint moment ratio lies in the variability of the rail support from tie to tie and from a group of two or three ties to an adjacent group, as indicated by the difference found in the values of the push-down and pull-up tests, in ways that are similar to the sources of the variability in stresses in rail that will be discussed in the next chapter. It is reasonably certain that with more nearly uniform rail support the average joint moment ratio would be higher and would more nearly approach the moment ratio of the rail opposite it (as would be desirable) than was found to be the case. The fit of bars and the play between rail and bar was generally satisfactory except in a few joints when the bolt tension was not sufficient to have drawn the bars into place. The deflection of the rail-joint in 66 in. was reasonably good considering the variability in the rail support. With a tension of 5000 lb. or more maintained in each of the six bolts it is evident that satisfactory action is developed in well fitting symmetrical bars that have been drawn into proper place. It seems evident that with more nearly uniform supports the average relation of the joint moment to the moment in rail opposite would be higher than the average value recorded, which was .75.

For the symmetrical form of bar used in this track, the stresses did not differ greatly from values proportional to the distance of the gage line from the horizontal geometrical axis, except as influenced by the general lateral bending of a joint due to conditions of the rail support. Such variations as were found rarely reduced the effective stiffness of the bar in a vertical direction more than 15 per cent, as found by a consideration of the inclination of the neutral axis obtained from the measured stresses.

**26. Stresses and Moments in Joint Bars at Mid-Section and in Rail Opposite with Heavy, Medium and Light Loads over Mid-Section.—**

The tests with heavy, medium and light loads show that for the track tested the stresses and moments in joint bars and in the rail opposite are not generally directly proportional to the applied load as would be the case if the modulus of elasticity of rail support were constant for the different loads and there were no play between rail and ballast bed or if this play were uniform from tie to tie. For uniform conditions the moments developed with the wheel loads of 30,000, 15,000 and 6500 lb. may be considered to be 260,000, 130,000 and 56,000 in.-lb., respectively—or proportional to 1.00, .50 and .22. It has been found that the smaller loads more frequently give relatively higher moments than are indicated by the above values.

Table 20 records the observed stresses in thousands of pounds per square inch at the various gage lines in the two bars of the rail-joints and at the outer and inner edges of the base of the rail opposite for the heavy, medium and light loads. It is apparent that the stresses at a given gage line are not generally directly proportional to the load. It is also apparent that the relative values of the stresses at gage lines 2 or 3 and 8 are frequently quite diverse for two loads and that the relative values in the two bars vary considerably. It is evident that there are lateral bending and twisting actions in the two bars and in the joint as a whole. Some part of these differences may be caused by differences in lateral thrusts caused by the load and by the position of the bearing of the wheels on the rails, though very little difference in the position of the wheel bearing on the rail was observable. A large part, however, is due to variability and eccentricity in the support of the rail on the tie-plate and tie and the support of the tie on the ballast bed both longitudinally and laterally—all combining to cause variations in the amount and position of the upward reaction upon the rail at consecutive ties when the load is applied and to produce variable lateral bending and twisting when the several loads are applied. Similarly, the stresses in the two edges of the base of rail opposite a rail-joint are relatively quite diverse in magnitude with respect to the weight of the heavy load and the medium load for the various locations at which tests were made. For example, at a point opposite joint 24 the stresses at outer edge and inner edge of base of rail are 9200 and 7600 lb. per sq. in. for the heavy load and 8400 and 3000 lb. per sq. in. for the medium load, while opposite joint 27 they are 4300 and 17,700 lb. per sq. in. for the heavy load and 1500 and 16,900 lb. per sq. in. for the medium load. It should be borne in mind that these differences refer to stresses and that the corresponding moments will not have the same relations.

The data of the stresses developed in the joint bars with the medium and light loads indicated that the average conversion ratio (ratio of moment calculated from gage line 2 and 8 to that from 3 and 8, referred to in the preceding article) as determined from the outer bar would not vary far from unity, and so the moments for the inner bar calculated from the stresses at gage line 3 and 8 were used without the use of a conversion ratio in the calculation of the moment at mid-section when the stress at gage

TABLE 20

**Observed Stresses at Mid-Section of Santa Fe Symmetrical Bars and at Base of Rail Opposite with Heavy, Medium and Light Loads over Mid-Section—130-lb. R.E. Rail—Tests on Chesapeake and Ohio Railway at Ashland, Kentucky**

The stresses are given in thousands of pounds per square inch for a load of 30,000, 15,000 and 6,500 lb. on each wheel of a four-wheel truck, designated as H, M, and L, respectively.

| Joint Number | Series | Load | Outer Bar |      |      |      | Inner Bar |      |      | Base of Rail |       |
|--------------|--------|------|-----------|------|------|------|-----------|------|------|--------------|-------|
|              |        |      | 1a        | 2    | 3    | 8    | 2         | 3    | 8    | Outer        | Inner |
| 22           | 43     | H    | 23.0      | 13.3 | 8.6  | 17.5 |           | 13.3 | 20.5 | 8.1          | 12.7  |
|              | 51     | M    | 14.1      | 6.9  | 5.5  | 12.2 |           | 8.9  | 15.5 | 4.6          | 12.4  |
|              | 36     | H    | 8.3       | 8.0  | 2.5  | 9.1  |           | 7.2  | 9.7  | 9.2          | 7.6   |
| 24           | 39     | M    | 5.8       | 7.5  | 2.5  | 6.9  |           | 4.4  | 7.2  | 8.4          | 3.0   |
|              | 40     | L    | 2.5       | 3.6  | 0.6  | 4.4  |           | 1.9  | 5.0  | 6.2          | 3.2   |
|              | 131    | H    | 14.1      | 13.6 | 8.6  | 8.0  |           | 7.2  | 12.2 | 1.7          | 13.7  |
| 26           | 136    | M    | 11.9      | 10.3 | 6.7  | 5.3  |           | 5.5  | 6.9  | 2.1          | 6.9   |
|              | 140    | H    | 14.4      | 17.2 | 9.7  | 13.9 | 11.4      | 9.4  | 11.1 | 4.3          | 17.7  |
|              | 139    | M    | 9.2       | 9.2  | 5.3  | 10.0 | 7.2       | 5.8  | 5.8  | 1.5          | 16.9  |
| 27           | 145    | H    | 25.8      | 19.1 | 13.6 | 18.9 |           | 16.6 | 10.8 | 11.5         | 8.9   |
|              | 148    | M    | 15.3      | 12.5 | 9.1  | 9.1  |           | 10.0 | 6.1  | 4.4          | 5.0   |
|              | 100    | H    | 12.2      | 13.3 | 8.3  | 11.4 | 15.3      | 11.6 | 14.7 | 7.1          | 9.3   |
| 41           | 103    | M    | 10.0      | 11.1 | 8.0  | 3.9  | 10.3      | 7.5  | 8.6  | 3.7          | 5.1   |

| 57           | 126    | H    | 7.2       | 8.9  | 5.0  | 5.8  | 10.5      | 7.2  | 8.0  | 5.2          | 5.6   |
|              | 125    | M    | 2.5       | 6.9  | 3.0  | 3.0  | 6.9       | 3.9  | 5.5  | 3.1          | 1.5   |

line 2 was not available. In Fig. 49 the moments at mid-section for two bars are plotted for the heavy and medium loads and also for the light loads when a test was made. In Fig. 50 the moments in the rail opposite the joint are similarly shown.

It will be noted in Fig. 50 that in a part of the tests on the rail opposite a joint the prolongation of the line joining the points for heavy and medium load or medium and light load would pass through or near the origin of coordinates so that for these tests the moment developed with the loads may be said to be directly proportional to the load. In others, the prolonged line would pass well above the origin, but in such cases the increase in moment above the lighter load is fairly near being proportional to the increase in load. It is evident that the larger development of moment with a small load is due to play between rail and ballast bed and that the rail bearings at points well away from the given section take proportionally greater reactions (even though small) than those near the section and thus have a greater than normal effect on the moment

Fig. 49.—VERTICAL BENDING MOMENT IN TWO JOINT BARS AT MID-SECTION FOR FIFTEEN RAIL-JOINTS—TESTS ON CHESAPEAKE AND OHIO RAILWAY.

Fig. 50.—VERTICAL BENDING MOMENT IN RAIL OPPOSITE A NUMBERED RAIL-JOINT—TESTS ON CHESAPEAKE AND OHIO RAILWAY.

developed. After fair bearings are obtained on all the ties the further moment developed may be expected to be proportional to the increase in load. The conditions opposite joint 43 are apparently abnormal or one set of readings contains errors; the moments are the same for medium and heavy load. It seems possible that the location of the other wheel on the same rail over a "hole" (see Fig. 65) may have developed differing negative moments under the rear wheel which gave this modification.

The moments in the joint bars plotted in Fig. 49 for the two or three loads show similar results. Generally the smaller load produces a larger moment proportionally than the next higher load, but the rate of increase in moment with increase in load is fairly proportional to increase of load. The same explanation holds for joints as for the full rail. Variations in play between rail and ballast bed more greatly affect the development of moment with the application of the first part of a load. Similar results were found with earlier tests. For the variation of depression at rail-joints with several loads see Fig. 86 of the Fifth Progress Report.

**27. Moments in Joint Bars at Mid-Section and in Rail Opposite with Heavy Load at Various Positions with Respect to the Rail-Joint.**—Stresses were observed at mid-section of the joint bars and in the rail opposite when the end wheel of the heavy load was over mid-section and also when it had been moved from point to point away from mid-section. The stresses were read at mid-section and in the rail opposite when an end wheel rested at 6 in. east of mid-section (retreating), and for part of the joints with wheel 24 in. away, and in a few with wheel at other positions, such as 12, 36, and 48 in. As would be expected from the conditions of the rail supports, the several positions of the load gave quite diverse lateral bending and twisting effects at mid-section of the different joints as well as varying vertical bending moments. These marked variations were found both in the rail opposite the joint and in the joint bars of the several rail-joints tested.

In Fig. 51 are plotted the vertical moments at mid-section calculated from the observed stresses for positions of the end wheel at various distances from mid-section for 8 joints and for the rail opposite, and likewise the corresponding moments in the full rail directly opposite the joint, thus forming experimental influence lines. A curve is also plotted from analytical considerations showing calculated values in the full rail as a wheel would retreat away from mid-section, based on a moment of 260,000 in.-lb. with a wheel over mid-section and a modulus  $u$  of 2600, giving the analytical influence line. Much of the variation from the analytical line is doubtless due to the variations in rail support, as well as to the differing conditions in the joints themselves.

In Fig. 52 the analytical value for the moment in the rail opposite the joint as a wheel moves away from mid-section is plotted considering the value of the moment for wheel load directly opposite the joint as 1.00—the moment becomes 0 when the end wheel is 24 in. from the given section. The average values of the moment in rail calculated from the stresses observed in the rail opposite a joint are plotted in the diagram for several positions of the load, as are also the moments found at mid-section of the joint bars. For some of the load positions, especially those at a distance from the section for the rail and joint considered, values were obtained at only a few joints, but the line drawn for the joint may be taken as representative of a composite influence line for the moment at mid-section of the joint bars. Similarly, the line for the rail section is representative of the influence line for the full rail. The values used in plotting the influence line for the rail did not include four locations for which the moment in the rail section with the wheel 6 in. away from the given section was considerably larger than when the wheel was directly over the section and for which the

Fig. 52.—COMPOSITE VALUES OF BENDING MOMENTS IN TWO BARS AT MID-SECTION AS THE WHEEL IS MOVED FROM POINT TO POINT AWAY FROM THE RAIL ENDS AND CORRESPONDING MOMENT IN RAIL OPPOSITE, EACH IN TERMS OF THE MOMENT WITH WHEEL AT RAIL ENDS AND OPPOSITE—CHESAPEAKE AND OHIO RAILWAY.

resulting influence line closely approached the curve of analytical values—an abnormal result doubtless due to peculiar or defective conditions of the rail support at ties near by.

**28. Stresses and Moments along the Joint Bars with Heavy Load over Mid-Section.**—For seven joints stresses were read at gage lines 2, 3 and 8 at sections 2, 4, 6 and 12 in. each way from mid-section with one wheel of the heavy load over mid-section, and in some of these joints similar readings were made for different conditions of bolt tension and for shortened joint bars. In several of these tests the stresses and the resulting moments along the bars were small, and, besides, in some cases the varying lateral bending in the rail and joints and the influence of observational errors on the results obscured the distribution of moment along the bars. In most joints the magnitude of the stresses in the upper and lower portions of the bars was nearly proportional to the distance from a horizontal axis, except as modified by lateral bending of the joints as a whole.

The shape of the moment distribution curve along the bar varied, depending on the fit, the vertical movement between bar and rail, and the tightness or looseness of the bolts. With good fit, little play, and medium or high bolt tension, the moment distribution curve showed a pointed or peaked condition throughout the middle of its length. Even with medium low tension and good fit the curve was pointed at the middle, as is

Fig. 53.—DISTRIBUTION OF STRESS AND MOMENT ALONG JOINT BARS IN JOINTS 22 AND 42  
—TESTS ON CHESAPEAKE AND OHIO RAILWAY.

shown for joint 22 in Fig. 53. In joint 42, with three loose bolts and quite a vertical movement at the rail ends the curve shown in the figure is rounding through the middle of the length and the bearing pressure of rail on bar is evidently spread over some little distance from the rail ends. The data of other joints having play and loose bolts show a flattening of the peak or a rounding. In joints having looseness of bolts and play, tightening of bolts gave a more pointed moment diagram. When the fit was excellent with low bolt tension there was little change in the shape of the moment diagram with

bolts tightened. With good fit and small play, for joints having a gage line at 12 in. from mid-section, the magnitude of the stresses was found to be small at 12 in. from mid-length.

The shape of the moment diagrams obtained indicated that with good fit and moderate or high bolt tension the centroids of the reaction forces fell at say 2 to 6 in. either way from mid-section for the interior reactions and 12 to 16 in. for the end reactions. The shape of the moment diagrams of three joints with low bolt tension or loose bolts indicates a single reaction on each half of the bar located about 12 in. from mid-section. In general, the moment developed at 12 in. from middle is relatively small. The stress data for the two pairs of bars cut to a length of 26 in. are not entirely consistent and do not extend beyond 6 in. from mid-length, but the moment developed at 6 in. from middle bears about the same proportion to the moment at mid-section for both long and short bars in the two joints used for this purpose. As a whole it may be concluded that nothing in the field tests indicates that the findings of the laboratory tests are not applicable to the conditions of the field.

**29. Vertical Play between Rail and Joint Bar and Deflection of Rail-Joint in 66 Inches.**—The measurement of vertical movement between rail and bar in a rail-joint upon the application of both heavy and light loads at mid-length of joint was made with a special Berry strain gage on 16 joints in their original condition and in some cases with modified conditions such as changed bolt tension and shortened length of bar. Measurement was made between the side of each bar and the side of the rail head near the ends of the bar and near the ends of the two rails and at two intermediate places near the quarter points of the length of the bars. Except where the bolts were loose, the magnitude of the vertical movement was generally small, ranging from 0 to .001 in. or sometimes to .002 in., although in some cases the movement at one or both rail ends was .005 in. or even more. At the middle of the length of the bars any vertical movement found was negative, a closing between head of rail and bar. At the ends of the bars a movement between rail head and bar generally was an increase and is called positive, though in a very few instances the distance decreased. At the intermediate points of measurement, any movements were small, except for the joints having considerable looseness, in which case the value was intermediate in amount between the values at middle and end with signs considered.

In Fig. 54 the vertical movements between head of rail and bar are plotted for joints with tight bolts, joints with loose bolts, joints with bolts tightened above the original condition and 26-in. bars not pulled into place and also with high bolt tension. Reference may be made to Tables 16 and 17 for the condition of the joints. In Fig. 54 bolt 1 is at the right end of each bar and 6 at the left end.

Of the joints with moderate to high bolt tension, joint 22 with the original moderate tension (series 43) gave little vertical movement for both heavy and medium load, 0, 0, 0, and  $-.001$  in. for the four measurements at the middle of the two bars and  $-.001$  to  $+.002$  in. at the ends. A .005 in. thickness gage was inserted between the bottom of the outer bar and the fishing surface of the rail from the end of the rail west for 6 in., both when unloaded and when loaded. At all other places along the two bars the thickness gage could not be inserted. It is seen that loading the joint changed the relative position of bar and rail very little. With the bolt tension increased to about 20,000 lb. (series 81) the thickness gage with the joint unloaded and loaded was inserted for a distance of only  $\frac{1}{2}$  in. instead of 6 in., and the vertical movements at the ends upon loading were a little smaller and those at the middle were not

Fig. 54.—VERTICAL MOVEMENT BETWEEN RAIL AND JOINT BARS—CHESAPEAKE AND OHIO RAILWAY.

changed upon applying load. In the test of joint 24 (all bolts tight—thickness gage not insertable anywhere) the measurements indicated no movements. For joint 26 (tight bolts) the measurements included seven at 0 and three at  $+.001$  in., but the two at the end of one rail were  $-.007$  and  $-.005$  in. and thickness gages could be inserted beneath the bars at these places only when load was applied. Joint 45 (tight bolts) showed 0, 0, 0 and  $-.002$  in. at middle and slight or no movement elsewhere; thickness gage could not be inserted at any place, either when unloaded or loaded. Joint 47 (series 22; presumably tight bolts) showed no movement except a slight one at the end of the inner bar. Joint 50 (with tight bolts, and no gage insertion, either unloaded or loaded) gave 0, 0,  $-.001$  and  $-.001$  in. at the middle and slight movement elsewhere. The above comments apply to results with both heavy and medium loads. It is apparent that the bars generally had good fit and that the movement between rail and bar was small except at one rail end.

For the tests of joints with low tension, one rail in joint 44 (series 15) apparently slipped in the bars from temperature change during the test between zero reading and reading with the heavy and the medium loads so that the values of vertical movement in the joint for both loads are evidently unreliable. From the tests with the shortened bars (series 63), however, it is probable that the vertical movements in the joint in its original condition were small. In joint 46 with bolt tensions from 2000 to 6000 lb. (series 8) the vertical movements for heavy and medium loads were zero or very small all along the bars, and the low load gave slightly smaller movements. Before load the gage was inserted from  $\frac{1}{2}$  in. east of the end of the east rail for 8 in. eastward but not upon loading. Joint 56 with low bolt tension gave larger vertical movements at the middle ( $-.003$  to  $-.014$  in.) and fairly small values at the ends ( $+.001$  to  $+.003$  in.); the medium load gave nearly the same results. The thickness gage was inserted at top or bottom of both bars through the middle 20 in. of the length of the bars. Except for the middle portion of joint 56, where thickness gage measurement showed considerable play and lack of fit, the low bolt tension of these joints gave only inconsequential vertical movement.

In the joints having three loose bolts or more the amount of the vertical movement varied but the values were greater than were generally found in the joints having tighter bolts. Joint 27 with west inner and west intermediate bolts having low tension and the other four bolts loose showed minor vertical movement at the middle of the bars and large movement at an end of both bars; the thickness gage measurements showed corresponding conditions. Joint 28 with all bolts loose also showed minor movement at the middle and large movement at the ends of a bar. The thickness gage was inserted at the ends of both bars at top both when unloaded and loaded and also at the top of the inner bar west for 8 in. from the middle; at the bottom under load only the thickness gage was inserted for 2 in. west of middle for outer bar and for 6 in. west of middle for inner bar. In joint 41 with three bolts loose and two with low tension, the end of one rail came closer to the outer bar by  $-.006$  in. and the end of the other rail closer to the inner bar by  $-.013$  in., but the largest movement elsewhere was  $.003$  in. At the bottom of the inner bar under load only the thickness gage was inserted for 5 in. west of the middle, the maximum space at west middle being  $.015$  in. In joint 57 with five bolts loose and one having low tension the movement at end of one rail was  $-.007$  and  $-.005$  in. and that at the east end of the bars was  $+.005$  in. and  $+.018$  in.—the other movements were moderate. At top of both bars at east end (both loaded and unloaded) the thickness gage was freely inserted for some distance, and at bottom of both bars west from middle for 7 in. In joint 43 with three bolts loose and two with

low tension and one tight the movements were small except that the east end with the loose bolts had a movement of  $+.003$  in. at the outer bar and  $-.003$  in. at the inner bar. The thickness gage showed good fit.

It is apparent that the form of this joint bar and its fit were conducive to keeping the vertical movements between rail and bar small or moderate when the bolts were tight or even when there was low tension. For joints having three or more bolts loose the movements were not very large in any joint. The small movement in the joint having two bolts loose and three bolts with low tension and the absence of very large movement in any of the joints also suggests the advantages of the 6-bolt joint regardless of the length of the bars.

As has been suggested elsewhere, the effect of tightening bolts in these joints depended on several different conditions—in some the vertical movement between rail and bar was decreased, in others no marked difference was found. Increasing the bolt tension in joint 22 to 20,000 lb. made little difference in the vertical movements, for the fit originally was good and the measured movement was small. In joint 46, changing the original tension of between 2000 and 6000 lb. to 12,000 lb. produced almost no change in the vertical movement. The same thickness gage insertions could be made for both conditions. For bars of joint 48 taken off and reapplied with a bolt tension insufficient to draw the bars into proper place with respect to the rail the vertical movement was hardly greater than that of the bars in their original position, and a tightening of the bolts acted to make only a small decrease in the movement. The original fit as shown by the thickness gage was fair, becoming very poor when the bars were reapplied with low bolt tension, and gaining good fit when bolts were tightened.

No great difference in fit was found when the 39-in. bars were sawed to 26 in. and reapplied in the same joint. In joint 44 in its original condition (series 15; bolt tension 1000 to 7000 lb.) the vertical movement at the middle of the inner bar was  $-.006$  and  $-.009$  in. With bolt tension of 2000 to 6000 lb. in the four bolts of the shortened bars (series 63) the movement of the inner bar at middle was decreased to  $.003$  and  $.002$  in., and with bolt tension of about 10,000 lb. (series 69) only small changes in these vertical movements were found. Thickness gage insertion indicated fairly poor fit of bars under the first condition and good fit under the second and third. When the shortened bars of joint 47 were installed with low tension (series 224) the vertical movement at the middle and ends increased somewhat over that of the original joint, and when high bolt tension was applied (series 230) the measurement was approximately the same as the small vertical movement observed in the original 39-in. bars. In the original 39-in. joint the thickness gage was inserted at top of outer bar for 5 in. east of middle, both unloaded and loaded. With the 26-in. bars applied with low bolt tension (not high enough to draw the bars properly into place), thickness gage insertion was slight at ends and middle of bars. With tightened bolts the fit was improved. It is apparent that for these two joints little difference in fit and in vertical movement for similar conditions of bolt tension was found between the lengths of 39 and 26 in. installed at the same point in track.

With reference to the effect of the magnitude of the load applied to the joint upon the value of the vertical movement between rail and bar, it may be said that for joints giving small movements there was little difference between the effects of the heavy and the medium load. For joints giving a larger vertical movement, in most cases the medium load gives a somewhat smaller movement, perhaps more nearly proportional to the moment developed in the joint. For the joints on which the low load was also applied, joint 46 gave negligible movements at all points for low, medium, and heavy

expected. The relatively small variation from the general rate of deflection means that the position of the centroid of rail pressure on the top fishing surface of the bar and that of the centroid of the reactions on the bottom fishing surface do not differ greatly in relative location regardless of bolt tension and looseness and tightness of joint, though of course some variation is apparent. It is evident, too, that there is little moment and therefore little curvature in the bars towards the ends of the 25-in. chord. The deflection in 37 in. also gives concordant results with reference to the moment developed at mid-section. As compared with the results with the 25-in. deflection bar they indicate relatively little bending curvature through the outer portions of the chord length. It was found also that the deflections of the outer bars in 25 in. and 37 in. gave good concordance with the deflections of the joints in 66 in. discussed in the preceding article.

In Fig. 56 are also plotted the deflection in 25 in. found in laboratory tests of the joints with the same Santa Fe symmetrical bar section of 26-in. length and applied moments of 120,000, 150,000 and 200,000 in.-lb. in one bar. The continuity of the results may be interpreted to mean that flexure of the 39-in. joint bars in the field tests and that of the 26-in. joint bar in the laboratory tests agree closely in position of centroids of bearing pressure and reactions and in deflections in 25 in. The field tests also include two joints with 26-in. bars.

The lateral deflection of either bar in 25 in. taken at the neutral axis of the bar was generally small, of the order of 0 to .002 in. or a little more, (either inward or outward) and had a more or less local character, so that the measurement cannot be taken to have general significance.

## V. TRACK DEPRESSION AND RAIL STRESSES IN TESTS ON THE CHESAPEAKE AND OHIO RAILWAY.

31. **Description of the Track.**—The tests were made in September and October 1931 on the westbound freight track of the three-track line of the Chesapeake and Ohio Railway (No. 1, the outer track on which the tests of rail-joints having the symmetrical type of bar were conducted), one and one-half miles west of Ashland, Kentucky. This track was built in 1924. On the tangent stretch on which the tests were made the embankment height was 4 ft. to 8 ft., except in the neighborhood of joints 26 to 28 where it increased to 12 ft. The roadbed evidently had become thoroughly compacted. There was 8 in. or more of heavy limestone rock ballast under the ties (large size broken stone free from fine particles) over a bed of gravel ballast which extended down 2 ft. or more. The stone ballast continued on one side to the ballast of No. 2 track and on the outer side it ran from 4 in. below the top of the tie, sloping outward with a full shoulder. Between rails (due to the recent re-surfacing) the ballast did not come within 2 or 3 in. of the top of tie. The ties were 8 ft. 6 in. long and generally about 7 in. deep. The width of the tie varied considerably, ranging from 8 in. to 12 in. The ties were treated oak. Most of the ties were laid in 1924, but some renewals had been made. All but a very few were in good sound condition, though a number were badly split at the ends. The rail was 130-lb. R.E. laid in March 1931. In laying the new rail, new tie-plates,  $7\frac{1}{2}$  by 12 in., with an eccentricity of  $\frac{1}{8}$  in. and an inclination of 1 in 28, were applied with only a limited amount of tie adzing. A cut spike was driven on either side of the rail. The rail ends were laid rather tight, and at the time of the tests a number of rail ends had been chipped somewhat. At the time of laying the new rail it is reported that the ties on the tangent track were not re-spaced and no general tamping of track was done at that time. About four weeks before the track tests were under

way, the ties were re-spaced to a certain extent, the ballast forked, and the ties hand-tamped with slight raising without adding more ballast. It was stated by the section foreman that the joint ties were tamped harder than the others. As will be described later, the tie spacing was not very regular, the tie-plate bearings were uneven and partially out of the rail base plane, and the unloaded rail failed to rest on the tie-plates for several consecutive ties from place to place along the track. Although the bearing of the tie-plates may not have varied much from ordinary practice the bearing conditions were quite in contrast with track with ties adzed and bored in such way as to ensure that all tie-plates have even bearing and lie in the same plane, as is the practice on some railroads. Nominally the cant of the rail was 1 in 28. Measurements made on the unloaded rail at 63 places along the track showed that on the north rail (on the side away from the other tracks) the range in the cant of rail was from 1 in 21 to 1 in 35 (averaging 1 in 27), and on the south rail from 1 in 13 to 1 in 23 (averaging 1 in 16). The difference in cant of the two rails was evidently due to differences in the adzing of the tie for the tie-plate bearing for the two rails along this stretch of track. The rail-joints have been described in Chapter IV.

The track carried very heavy freight traffic. At the time of the tests, fifteen or more trains of 110 to 130 loaded coal cars of 50- and 70-ton capacity moved westward during the day, most of which were diverted to track No. 2 for accommodation of the test work. The information was given that during this time the movement of traffic which would regularly go to track No. 1 was at the rate of 60,000,000 tons a year, which though not up to the normal traffic is exceedingly heavy. In fact, this stretch of track is known as having the heaviest tonnage on the road and this tonnage is rarely if ever exceeded on any railroad. It is evident, then, that four weeks of this heavy traffic would be likely to bring the track surface down to what may be considered to be normal surface conditions. It should be noted that the speed of these heavy trains was slow, never over 25 miles per hour.

**32. Methods of Testing.**—The same steel hopper coal cars of 70 tons capacity were used as in the tests of the rail-joints. As before, the loads on the test end of the cars were 26,000 lb. for the light load, 59,500 lb. for the medium load, and 119,800 lb. for the heavy load, which have been called 6500 lb. per wheel for the light load, 15,000 lb. for the medium load, and 30,000 lb. for the heavy load. In tests of track depression, the car was kept in place until levels had been taken on rail and tie and tie-plate along the given stretch of track. In one test the levels were taken only at the tie just below the end wheel for spottings on seventeen consecutive ties. For the tests to find stresses in rail an end wheel was spotted at the desired point, generally directly over a tie, and after the measurements were made the car was moved to the next point, and thus on from point to point along the rail. The stresses in rail were measured at the two edges of the base of rail at gage lines just inside the upper outer corner of the rail base and 0.52 in. vertically above the bottom of the rail, using a Berry strain gage of 2-in. gage length.\* As in the tests of rail-joints the Berry strain gage was used by a skillful and experienced operator and it is believed that because of the smaller chances for temperature variation in the shorter intervals of time required for taking the data the results are subject to less error than those for the rail-joints. In the measurement of stresses in rail only the heavy load was used except at points opposite the rail-joint. Zero strain

---

\* A reference to a description of the Berry strain gage and its use is given in Article 6 "The Laboratory Tests of Rail-Joints".

gage readings were taken before the load was applied and afterward. The deflection of the rail was taken with a 66-in. deflection bar at points opposite the rail-joints tested.

The method of determining the track depression involved taking levels along the track with an engineer's level for the track unloaded, loaded with light, medium, and heavy load, and again in an unloaded condition. The level was also used in making push-down and pull-up tests. A special level rod (see Fig. 93) 6 in. long with the scale graduated to one-hundredth inch was generally read to one-hundredth inch but sometimes half-hundredths were read in getting the vertical movement between rail and tie-plate, tie-plate and tie, and for other purposes. A spherical bubble attached to the level rod aided in giving accuracy. The levels were taken with the pointed end of the level rod placed in a punch mark in the base of the north rail near its outer edge above the middle of the width of each tie and in a punch mark on a nail in the tie about 1 in. away from the outer edge of the north tie-plate, and also at the south rail for the two ties between the wheels of the rear truck. For each test location these levels were taken at each individual tie from a tie about the middle of the length of the test car to a tie about 15 ft. behind the rear wheel of the rear truck. The engineer's level was placed about 10 ft. from the rail and opposite the space between the two wheels of the rear truck. Check readings were taken on nearby bench marks. To insure accuracy one man carefully kept the instrument level while another took the readings. Levels on punch marks on a few tie-plates near the wheels of the rear truck were also taken. Other observations were made for special purposes. It should be noted that the frequency and length of trains on the other two tracks put practical obstacles in the way of taking levels along the south rail except for the two ties between the wheels of the rear truck as noted above. Information on the stiffness of track along the south rail would have been of value in making comparisons.

**33. Tests of Track Depression.**—From the tests of track previously made, it is to be expected that the depression of rail caused by the application of a light load will be greater proportionally than that of heavier loads and that the added depression of the heavier loads will in general be approximately proportional to the difference in the two loads. It is also to be expected that part of the rail depression found with both light and heavy loads will be due to play existing between rail and ballast bed and hence this portion should not be considered in determining the stiffness of the track.

In Fig. 57 to 61 the results of the gross depression measurements of rail and tie for light, medium, and heavy load for the five locations at which levels were taken are plotted as ordinates at each tie including six ties at each end away from the two wheels of the car truck, and for convenience these points are connected by lines. The dashed line at the upper part of each diagram (named the derived play curve) represents the play between the rail and the tie bed as found by subtracting from the gross depression with the light load a quantity found by multiplying the excess of the gross depression with the heavy load over that with the light load by the ratio that the excess of weight of the heavy load over that of the light load bears to the weight of the light load. This calculation is based on the assumption that the light load has brought both rail and tie to a firm bearing at each tie and that the further depressions made by the heavy load are everywhere proportional to the added load taken by individual ties. However, it will be seen by Article 35 that in some cases the light load has not produced a firm bearing at some of the ties. It should be noted that the depression measurements toward the ends of the diagram and the derived play at the same places are not representative of the individual tie load conditions at this part of the diagram for the reason that the actual

Fig. 62.—GROSS DEPRESSION OF RAIL AND TIE AT THE REAR WHEEL WHEN THE LOAD IS MOVED FROM TIE TO TIE—LIGHT AND HEAVY LOADS—TOGETHER WITH DERIVED PLAY CURVE—TESTS ON CHESAPEAKE AND OHIO RAILWAY.

vertical play of rail and tie at these places is generally greater in amount than the gross rail and tie depressions. It should also be noted that upward movement of the rail and tie will not be representative of actual negative vertical pressures acting on the rail. By comparison with the data of the pull-up and push-down tests in Fig. 64, 65, and 66 it will be seen that the ordinates of the curves marked "derived play" in Fig. 57 to 61, though usually in fair agreement with the sum of the pull-up and push-down tests except at or near the ends of the length of the diagram, are frequently somewhat less than this sum, because of the fact that the light load has not brought the rail down to a fair bearing at every tie and that the rail has bridged over two or more tie spaces. Examples of this failure to take load are indicated by an asterisk in the figures.

Tests were made by spotting the end wheel of the car truck at points immediately over consecutive ties, beginning at joint 44 and running west on the north rail and measuring the rail and the tie depression directly under this wheel by means of levels at each of seventeen load positions, no readings being taken at points away from the wheel. At the top of Fig. 62 are plotted the measurements of rail depression for the light load and the heavy load and at the bottom the corresponding tie depression; a plotting of the derived play curve for the rail is also shown. It is evident that both rail depression and tie depression have considerable variation along the track. The depression of the rail at the highest point of the curve for the heavy load is .18 in. and that at the lowest point is .33 in., and the range in the position of the play curve is from .02 in. to .14 in. Not only is the range great, but it must be true that the stiffness of the 130-lb. rail acts to bridge over many inequalities in the rail support and that without this stiffness its variability would be much more apparent. The variability in the gross depression of the tie directly under a wheel load given in the lower part of the diagram is marked and erratic. This is due largely to the variation in the play between rail and tie along the track.

In Fig. 63 the net depression of the rail and the tie in the consecutive tie loadings given above for the light load and for the heavy load is shown, the value having been obtained by subtracting the ordinate for the derived play curve from the corresponding gross depression at every tie given in Fig. 62. The line of net rail depression for the light load seems fairly uniform but by comparison it is seen that the value at the lowest point is 50 per cent greater than that at the highest point. This ratio likewise holds true for the corresponding points in the line for heavy loads. The values for the net tie depression have considerable variation—ranging from .09 to .19 in. for the heavy load. It is evident that the variation in tie load for a given spot may be even greater than is indicated by the variation in net ordinates, for the stiffness of the rail helps to place upon stiffly bedded ties much greater loads than their normal share.

**34. Elements in the Total Rail Depression.**—The vertical movement between the rail and the tie's bed in the ballast may be considered to be made up of (a) play between rail and tie-plate, (b) play between tie-plate and tie including any vertical movement of tie-plate due to imperfect bearing of tie-plate on the adzed surface, (c) compression of the tie throughout its depth when load is applied through the tie-plate, and (d) play between bottom of tie and its ballast bed including bending of the tie to reach the bed directly under the rail. Below the tie bed the elastic vertical compression of the ballast still further increases the downward vertical movement of the rail under load by .05 to .15 in. for stiff ballast and medium to heavy loads. The inelastic down-

ward movement of the ballast, after the track has been in use, is extremely small and may be neglected for the purpose in mind.

Tests were not made to determine precisely the division of the play among the several vertical movements between rail and tie bed. The vertical movement between rail and tie-plate was markedly large, ranging from 0 to .15 in. or more. This play between rail and tie was quite variable from tie to tie and from a group of two or more ties to another group of ties. This variability in the play is an important source of the marked variation in stress in rail found from point to point along the track. The heads of the spikes in most cases were found to be high enough above rail contact to permit full play.

Fig. 63.—NET DEPRESSION OF RAIL AND TIE AT THE REAR WHEEL WHEN THE LOAD IS MOVED FROM TIE TO TIE, TOGETHER WITH MODULUS OF ELASTICITY OF RAIL SUPPORT CALCULATED FROM RAIL DEPRESSION AT REAR WHEEL—TESTS ON CHESAPEAKE AND OHIO RAILWAY.

Although the average play between tie-plate and tie was not large over the whole tie-plate, there was evidence of sufficient unevenness of bearing between tie-plate and tie to give eccentric reactions between the rail and the tie, which contributed largely to the variability of stress at the two edges of the base of rail and to twisting in the rail. Similarly differences in the planes of the base of rail and the bearing face of the tie-plate caused eccentric reactions.

As is reported elsewhere, the play between tie and ballast bed was found to be small (generally 0 to .03 in.)—that is, the ties were not generally held up above the ballast bed by the rail and spikes—but of course flexure of the tie to fit the tie bed was generally developed under the load.

35. **Vertical Play or Looseness between Rail and Tie and between Tie and Ballast Bed.**—A purpose of the tests was to learn what vertical play or looseness exists at individual ties between rail and tie and also what exists between tie and ballast bed. The test to find the play between tie and ballast bed is termed the push-down test and that for the play between rail and tie the pull-up test, the later term being substituted for "hook-up" used in the Fifth Progress Report. In these tests levels were taken accurately on a nail inserted in the tie about 1 in. away from the outer edge of the tie-plate, both for the original position of the tie and when a downward or an upward force was applied to the tie. The level readings were taken at both rails and on the two ends of a tie. In the few cases where the spike did not have full clearance from rail base it was pulled slightly to allow clearance.

In the push-down test a bar was placed under the rail head and over a fulcrum block resting on the tie at the gage side of the rail, and downward pressure was exerted by a man at the further end of the bar. The resulting pressure on the tie (probably about 1,000 lb.) was usually sufficient to set the one end of the tie fairly well on its ballast bed or at any rate to hold it very nearly in that position. The difference between the level readings on the tie before and when the force was applied gives the vertical movement required to seat the one end of the tie on its ballast bed at the given end. In most cases where the movement was large the other end of the tie rose somewhat.

The pull-up test was made by inserting the bar through ballast under the end of the tie, using a short block as a fulcrum, and applying pressure at the further end of the pry. The effort was made to exert just enough pressure on the pry to bring the rail and tie-plate and tie into contact, and level readings were then taken. The difference in the readings on the tie for the original position and for that taken when the force was applied gives the play between rail and tie.

It should be understood that the method of making the pull-up and push-down tests was not closely accurate. The amount of the force exerted on the lever in the pull-up test may sometimes have been too great, and the rail itself may have been lifted somewhat. Possibly some ties may have rocked or tilted on a support at their center and there may have been lateral twisting in the position of the tie. In some cases the push-down test may not have seated the tie fully on its whole bed. However, the method was readily and quickly applied, the possible errors were small, and the results are considered to be significant.

The values of the movement between tie and ballast bed found in the push-down test are usually small—generally .01 in., frequently .02 in. and in 35 places out of 434 observations the movement was .03 to .05 in. This means that ordinarily when the rail is without load the ties generally lie fairly on one or more points of the ballast bed. It should be noted that this is the usual position taken with a very light load; it does not mean that the tie is in contact with its ballast bed all along its length, for the loaded cars will put flexure into the tie, bending it to fit the curved ballast bed, and of course it does not include the depression of the ballast bed itself when loaded wheels are applied to the rail.

The results of the pull-up tests indicate the amount of vertical play between rail and tie in an unloaded condition, and those of the push-down tests the amount of the vertical play between the unloaded tie and its ballast bed. To show the distribution and the grouping of the variability, the data for several stretches of track have been plotted

Fig. 64. VERTICAL PLAY BETWEEN RAIL AND TIE AND BETWEEN TIE AND BALLAST BED AS DETERMINED BY PULL-UP AND PUSH-DOWN TESTS—TESTS ON CHESAPEAKE AND OHIO RAILWAY.

Fig. 65.—VERTICAL PLAY BETWEEN RAIL AND TIE AND BETWEEN TIE AND BALLAST BED AS DETERMINED BY PULL-UP AND PUSH-DOWN TESTS—TESTS ON CHESAPEAKE AND OHIO RAILWAY.

in Fig. 64, 65 and 66, with values obtained at every tie for both the north and the south rail. The distance of one set of points below the base line gives the vertical distance measured from the normal position of the unloaded rail to the resting position of the unloaded tie, as found by the pull-up test, and these points are connected by a light line. The distance from the resting position of the bottom of the unloaded tie to a position on its bearing bed directly below the rail, as found by the push-down test, is plotted downward from the points on the light line, and the points so plotted are connected by a heavy line. The ordinates of the heavy line then represent the total vertical play between rail and tie bed. Owing to the method of lifting the tie used in the pull-up test an error of observation of .01 in. or possibly of .02 in. may occasionally have been made, and consequently an individual point may be considered to be subject to inaccuracies of the order of these amounts. To aid in interpretation it may be remarked that a continuous 130-lb. rail supported every 15 ft. will deflect less than .01 in. under its own weight and that even if the supports are unevenly spaced the maximum deflection in this length will generally not exceed .01 in. The tests recorded in Fig. 64, 65 and 66 include track at and near the location of all the tests on rail joints, rail stresses, and track depression, and for the most part values are given for consecutive ties.

The total play given in Fig. 64, 65 and 66 varied from 0 to .19 in. and one value of .25 in. The average for the 434 measurements was about .064 in. The most significant feature of these values lies in the variation in play from tie to tie or from a group of from two to five ties to another group of ties lying adjacent in either or both directions. It is seen that the variation in grouping and in depressions is large and varied and results in abrupt and frequent variations in the rail support. Sometimes the rail touches the tie at adjacent ties and sometimes no contact is made for twelve ties or more. It is seen from the figures that hills and hollows are grouped in various combinations ranging in clusters from three or four to ten or twelve ties. A study of the diagrams is of interest then in indicating stretches of rail without support, in showing groups of high ties and low ties, and in bringing out the markedly uneven contour of the rail support. A tie fairly close to the rail may be called a high tie and on this stiff ballast one more than, say, .04 in. below the rail a low tie. As an example, in Fig. 64, on the north rail one support for the unloaded rail is six tie spaces east of joint 22 and the next is three tie spaces west, while to the right the next six ties are fairly well below the rail, and to the left the next three ties are somewhat below the rail. On the south rail opposite joint 26 the unloaded rail has no support for six ties, then four ties give support, then four ties give poor support. A deep depression of the rail support is apparent near joint 56 in Fig. 66. Some ties and groups of ties will take abnormally high loads and others will take no load until the high ties have been depressed an abnormal amount or the rail bent so the low ties may receive load. It is evident that the supporting values of the ties when under load are very irregular and extremely variable from place to place along the track. This unevenness, it will be found, has an important and disturbing effect on the individual tie reactions when the load is applied to the rail and upon the intensity of the stress in rail at the high ties and the low ties along the track.

36. **Variation in Load Taken by Individual Ties.**—It is evident that play between rail and tie bed results in variations in the load carried by individual ties as the train passes over the track. The relative amount of load taken by individual ties may be estimated with a fair degree of accuracy for the purpose of comparison from the measurements of the pull-up and push-down tests and the amount of the average net rail depression for a given set of wheel loads by assuming that the total load is carried by a certain number of ties and that the load carried by an individual tie is proportional to the amount of the net depression of the tie when the load is applied—that is, to

Fig. 66.—VERTICAL PLAY BETWEEN RAIL AND TIE AND BETWEEN TIE AND BALLAST BED AS DETERMINED BY PULL-UP AND PUSH-DOWN TESTS—TESTS ON CHESAPEAKE AND OHIO RAILWAY.

the amount the tie depresses after the play is overcome and it starts to take load. To make a simple illustration, one not likely to be found in track, suppose each alternate tie has a vertical play of .07 in. and that the remaining ties take load from the start. Consider also that the given load would produce a rail depression of .07 in. if supported

uniformly by all the ties. Then calling  $y'$  the rail depression for uniform support and  $y$  the depression for the ties under the conditions assumed,

$$y' = .07 = \frac{1}{2}(y + y - .07)$$

$$y = .105$$

It follows that the load carried by the high ties will be 1.50 times the average tie load and that by the low ties only .50.

If the play at the alternate ties were .14 in. and the depression under uniform tie support remained .07 in., then the high ties would take 2.00 times that for uniform tie support and the remaining ties would take nothing. On the other hand, if the track substructure is less stiff and the depression on a uniform support is .21 in. for the given load instead of .07 in. and the vertical play of alternate ties remains .07 in., the high ties will take only 1.17 times the average load and the low ties .83 times the average load. It follows that for the same range of vertical play a stiffly supported rail may be expected to have a greater variation in tie loads than a rail less stiffly supported.

Fig. 67.—ESTIMATED DIVISION OF LOAD AMONG CONSECUTIVE TIES BASED ON PULL-UP AND PUSH-DOWN TESTS—1.00 REPRESENTS UNIFORM DIVISION—TESTS ON CHESAPEAKE AND OHIO RAILWAY.

For a careful determination of the reactions the full length of the depressed track will of course need to be taken into account, but for obtaining approximate values the inclusion of a few ties outside the wheel group in making the calculations of track depression will permit a fair comparison to be made.

As examples of quite variable conditions found in the track, Fig. 67 gives plottings of total play between rail and tie bed taken from the pull-up and push-down tests for

groups of ties at four locations. To get a conception of the variation in the distribution of load among the various ties, consider that for a medium load 90 per cent of the 30,000 lb. load on the two wheels is carried by six ties and that the average net rail depression at these six ties is .07 in. Consider further that the stiffness of the rail would produce approximately equal depression for these six ties if no play existed. On these assumptions the division of load among the six ties will be represented by the vertical lines, the values being given in terms of the load carried by uniformly loaded ties as unity, as would be approximately true with absence of play. It will be seen that the range in individual tie load is from 0 to 2.7 times the average tie load. The four diagrams shown were selected at locations which give a striking variety of distribution of tie loads. It is evident that with such groupings of tie loads great variability in bending moments will be developed in the rail at different points.

If the heavy load (60,000 lb. on two wheels) had been used, the variations from average load of course would not be so great. For the play given in the upper right hand diagram of the figure, the proportion taken by the tie at the right is 1.8 instead of 2.7, but the two middle ties take .3 and .6 times the average load. In the upper left hand diagram the ratio 1.8 drops to 1.40. The distributions even with the heavy load are far from uniform.

A study of the amount and distribution of the vertical play between rail and ballast bed recorded in Fig. 64, 65 and 66 shows that there are many variations in play and in the groupings of play at different places along the track and therefore that there must be great variability in the amount and distribution of individual tie loads. Approximate calculations made on the assumption that the load carried by a tie is proportional to the further depression of the rail after the play at the given tie has been overcome emphasize the part that the distribution of the variation in play must have in modifying the magnitude of individual tie loads and the stresses in rail from point to point along the track. For the medium load of 15,000 lb. on each wheel of a freight car truck two adjacent ties may take 0 and .1 of their share of the load and one tie beyond each way may take more than their share. Other cases are found where one tie takes more than twice its share of load and adjacent ties less than half of their shares. Variations of a third more or less than the normal share are frequent. It is evident that two kinds of consequences result from these variations—(1) the abnormally heavy loads give undue load effects on certain ties and the ballast underneath, and (2) when ties carrying no load or light loads are between ties having little or no play the stresses in the rail must be markedly increased. The first effect results in lack of uniformity in wear and maintenance; the second may cause injurious effects in the rail—both contribute to roughness in track and require increased maintenance.

Again it will be seen that the variations in the tie loadings will be relatively less marked with the heavy load, but the difference will still affect the tie and ballast loads. It will also be found that the variations in stress in rail are very marked for the heavy load. The principal source of the variations in stress may be traced to the variations in rail support.

**37. Values of Modulus of Elasticity of Rail-Support  $u$ .**—In the analysis of the action of track as an elastic structure under load, the term modulus of elasticity of rail-support  $u$  is introduced as a measure of the vertical stiffness of the rail support. It is defined as the pressure per unit of length of each rail required to depress the rail one unit. It represents the vertical stiffness of the ties, ballast and roadway, but does not involve the stiffness of the rail, though of course the flexure of the rail in the track is affected by the value of this modulus in the manner set forth in the analysis. For the

units in use on American railroads, the value of this elastic constant is expressed in pounds per inch of length of one rail per inch of average rail depression.

The accompanying vertical reaction or vertical force against the rail (principally an upward force) on the assumption of a continuous elastic rail support and a constant modulus  $u$  has a relation to the vertical depression of the rail in the analysis given by the equation

$$p = -uy \dots\dots\dots (6)$$

where  $p$  is the upward pressure against the rail per unit of length of rail at any given point (intensity of pressure) and  $y$  is the depression of the rail at the same point. For a given wheel load or group of wheel loads it is evident that the sum of the wheel loads on one rail will be equal to the sum of the reactions against the rail found by substituting the average of the rail depression throughout the length of the depression curve in this equation and then multiplying the resulting value of  $p$  by the length of the depression curve. The general form of the depression curve given by the analysis for two wheel loads of a truck is shown in Fig. 68. For the parts of the curve that rise above the original position ( $AB$  and  $EF$ ) the analysis assumes that the uplift involves a downward pull on the rail proportional to the uplift and dependent upon the same modulus. The reaction forces are continuous and at any point vary in magnitude in proportion to the ordinate of the rail depression curve, whether positive or negative.

Fig. 68.—FORM OF RAIL DEPRESSION CURVE FOR TWO WHEELS GIVEN BY ANALYSIS.

The analysis and formulas for the action of track as an elastic structure, referred to above, are given in the First Progress Report of the Special Committee on Stresses in Railroad Track (Proceedings, A.R.E.A., Vol. 19, 1918). A further application of the analysis is given in the Second Progress Report (Proceedings, A.R.E.A., Vol. 21, 1920). The equations for moments and depressions and other properties, as well as the master diagram, are repeated in the Fifth Progress Report (Proceedings, A.R.E.A., Vol. 31, 1930). Equations (7), (8), and (9) are given in Article 56 "The Analytical Consideration of Depressions, Stresses and Moments in Rail" of this report, and the master diagram for depressions and moments is also reproduced in Fig. 88.

Although the rail support in the track is not continuous, with the close spacing of ties generally in use and for values of  $u$  obtained from the track as built the analysis applies fairly accurately for well-built and well-maintained track so far as the discontinuity of the rail support is concerned. In the analysis it is assumed that beyond the ends of the downward part of the depression curve there is for some distance an upward depression where the pressures act negatively with values that are still proportional to the  $u$  of the depressed track. The amount of this assumed negative pressure will generally be greater than the weight of the rail in the case of the heavier wheel loads. Since in ordinary track the tie will not be lifted with the rail by the spikes throughout this small upward depression and as the weight of the ballast generally is not tributary to the negative pressure the stretch of track beyond the downward depression will not entirely conform to the assumptions of negative pressure used in the analysis. The greatest upward movement calculated by the analysis for ordinary track

is about .02 in., a seemingly small value. For the two wheels of the freight car truck on one rail of a stiff track the magnitude of the downward pull on the upward part of the depression curve obtained by the analysis sums up at each end ( $A$  to  $B$  and  $E$  to  $F$ , Fig. 68) to about 3 per cent of the total load on the two wheels, an amount that is too small to need be considered in a determination of  $u$ . However, it should be stated that this small upward force situated at a relatively large distance from the wheels does have an important influence on the magnitude of the moment at and between the wheels.

A further word may be given in regard to the downward pull on the rail at the two ends of the depression curve. If the weight of the rail is the principal source of this downward pull, the rail may be expected to be free from its support when it rises as much as .005 in. (not counting the vertical play), and its full weight will be at once available. Because of the stiffness of the rail its weight may be brought into action for a greater distance along the track than is indicated by the analysis (and lifted higher) and this and the greater leverage of this longer length apparently largely compensates for deficiency in intensity of downward pull called for in the analysis.

Fortunately it is found even with variations from the assumed conditions that calculations based on the analytical method usually give values of the moments and the depressions throughout the main portion of the depression curve that for the heavier loads are fairly close to the average measured values, particularly when  $u$  is obtained by means of measured depressions throughout the depressed part of the curve on the same or similar track. Furthermore, the agreement will be closer in the case of a group of wheels like locomotive drivers and the wheels of a truck or of two adjacent trucks of coupled cars, where the analytical upward depressions due to one wheel act at a second wheel only to decrease the analytical downward values at the second wheel, so that the analysis for such loadings would not usually involve an actual development of upward depressions between wheels, and thus the lack in upward pressure is confined to points well beyond the outside wheels of the group. It is also apparent that within a group of wheels the analytical negative moment from one wheel acts at any given point to modify the analytical moment from an adjacent wheel at the same point and that under certain conditions a resulting negative moment will be developed at points between wheels. It may be concluded from information obtained in the tests to find the value of  $u$  and from experience in applying the analysis that the deficiency in negative pressures referred to may not be expected to affect the general usefulness of the applications of the analytical method in calculating the moments and depressions of the rail throughout the greater portion of the length of the depressed track.

A second element of variation from assumed conditions also needs consideration. For the usual conditions of track, play exists between rail and tie and tie and ballast bed in varied and irregular amounts from tie to tie, and this variability modifies the distribution of the upward pressure on the rail from tie to tie along the track. For this condition the assumptions that a fair bearing is generally reached at nearly every tie on the application of the light load (even though the load carried by consecutive ties may differ greatly) and that the further tie reaction at any tie is proportional to the further depression of the rail are useful approximations.

In the determination of  $u$  given in previous reports of the Committee the assumption was made that all the ties through the depressed length of the curve to or almost to the point where downward depressions change to upward ones carry load and should be included in the determination of  $u$ . It is apparent that this procedure gives values of  $u$  somewhat lower than the actual modulus because with large play or even medium play between rail and ballast bed there will probably be two or three ties at the ends of the

downward depression curve that will carry little or no load; that is, the play will prevent the rail from transmitting to these ties pressures of sufficient magnitude to be considered in the computations.

A study of the pull-up and push-down tests and the rail depression curves with light load and heavy load will show that ties near the end of the depressed length usually develop little or no reaction upon the application of the wheel loads and that these ties frequently should not be included in the number of bearing ties at which rail depressions are used in the calculations when the play at these ties exceed the corresponding values for the rail depression. On the track of the Chesapeake and Ohio Railway the load-carrying ties in the several test locations extend usually three ties beyond or outside the position of the two wheel loads and sometimes one or two ties further, and hence in the computations only the ties between these limits have been considered. At some of these locations one or more ties through the main portion of the depression curve were found by the pull-up and push-down tests not to be in condition to take reactions under the light load. However, it has been thought best to disregard those imperfect bearings, though a consideration of the deficiencies in these tie reactions would tend to increase the value  $u$  obtained from a given set of data.

The curves marked "derived play curves" in Fig. 57, 58, 59, 60, and 61 were obtained from the data of the tests on the assumption that the light load overcame the play at all ties and that the further rail depression beyond that of the light load (net depression) will be proportional to the added load given by the heavy load. The difference between the value of the rail depression for the heavy load and the ordinate of the derived play curve at any tie that carries load will be called the "rail net depression ordinate", this long term being used instead of "net rail depression" to avoid confusing these ordinates with the ordinates of the flexure curve of the rail itself. Under the assumptions used the load carried by an individual tie will then be proportional to the rail net depression ordinate. In Fig. 69 the rail net depression ordinates at the five test locations obtained as described above for the heavy load have been plotted for all the ties that are considered to carry load. Reference to the measurement of play between rail and tie bed found in the push-down and pull-up tests and recorded in Fig. 64, 65 and 66 indicates that ties near the end of the depressed length frequently do not carry load even on the application of the heavy load or possibly may take load only after the play has been overcome. Accordingly at the ends of the depressed length the ordinates in the figure indicate rail net depression values only to the amount given by the pull-up and push-down tests. Connected by dotted lines in the figure (Fig. 69) are also plotted values at ties at the ends of the depressed length found by means of the derived play curve but not considered to represent load carrying depressions.

In calculating the value of  $u$  for a given test location, the rail net depression ordinates at each tie considered to carry load are added, and the total wheel load on the one rail is then divided by the product of this summation of the rail net depression ordinates and the average tie spacing through the depressed length. This procedure assumes that the total upward reaction is equal to the summation of the useful depressions at the ties throughout the depressed length multiplied by the average tie spacing and by  $u$ , and that this reaction is numerically equal to the wheel loads on one rail. As an example, if the summation of the rail net depression ordinates at location 1 is 1.11 in. for 11 ties and the average tie spacing is 21.3 in. and the load of the two wheels on one rail is 60,000 lb., the resulting value of  $u$  will be 2500 lb. per in. per in.

In Table 21 are given the values of  $u$  for the five test locations calculated from the data plotted in Fig. 69. The range is from 2200 to 2900 and the average value is 2600 lb. per in. per in. These values indicate a stiff rail support, and the range in values is

Fig. 69.—RAIL NET DEPRESSION ORDINATES FOR LIGHT AND HEAVY LOADS AT FIVE TEST LOCATIONS—TESTS ON CHESAPEAKE AND OHIO RAILWAY.

relatively small. In passing it may be well to note that each of these values was obtained by the use of depressions at a number of ties and should be thought of as averages, and that on account of the marked variation in play from one or more ties to another small group of ties the stress developed in rail from point to point may be expected to be greater or less than the stress calculated from these average values of  $u$ .

An approximate method of deriving values of  $u$  consists in substituting the average of the two net rail depressions at the two wheel loads in the analytical equation for the depression at the two wheel points, which for the wheel spacing used and the average stiffness of the track tested becomes

$$u = k \sqrt[3]{\frac{P^1}{64 EI y_1^4}} \dots\dots\dots (9')$$

where  $P$  is the weight of one of the two wheel loads,  $y_1$  the average net rail depression at the two wheels,  $E$  the modulus of elasticity of steel,  $I$  the moment of inertia of the rail section, and  $k$  the ratio of the depression at the two wheels to the depression at a single wheel for any given conditions. This procedure makes the value of  $u$  dependent upon the depression at the two wheel points only, instead of averaging the depression along the depressed length of track. Equation (9') is obtained by finding by the analysis and master diagram of the First Progress Report (see Fig. 88 of this report) the ad-

TABLE 21

### Modulus of Elasticity of Rail-Support $u$ —Tests on Chesapeake and Ohio Railway at Ashland, Kentucky

The values of  $u$  are given in pounds per inch per inch of one rail. Heavy load is 30,000 lb. on each wheel; medium load is 15,000 lb.

| Location | From Summation of Rail Net Depression Ordinates |             | From Net Rail Depression at the Two Wheels Heavy Load |
|----------|-------------------------------------------------|-------------|-------------------------------------------------------|
|          | Heavy Load                                      | Medium Load |                                                       |
| 1        | 2500                                            | 2000        | 3000                                                  |

| 4        | 2600                                            | 2400        | 2700                                                  |
| 5        | 2600                                            | 2000        | 2900                                                  |
| Average  | 2600                                            | 2300        | 2800                                                  |

ditional depression at one wheel position given by the second wheel load for an assumed value of  $u$  and for the given distance between wheels, then expressing the depression at and for a single wheel load ( $y_0$ ) in terms of the depression for the two-wheel load ( $y_1$ ) (thus,  $y_0 = \frac{y_1}{k}$ ), substituting this value of  $y_0$  in equation (9) of the First Progress Report, and solving  $u$  to the form given in equation (9'). The value of the coefficient  $k$  which fits the conditions of  $u = 2600$  in equation (9') is 1.29. If the resulting value of  $u$  differs from 2600 by 20 per cent, an error of 2 or 4 per cent in  $u$  may obtain. For other conditions of stiffness, distance between wheels, and weight of rail, a suitable average coefficient  $k$  may be calculated for use in place of 1.29 named above.

The value of  $u$  obtained by using the average net rail depression at the two wheels in equation (9') for each of the five locations for the heavy load, given in Table 21, is

somewhat larger than the corresponding value obtained by the use of the sum of the rail net depression ordinates. The average for the five locations is 2800 as compared with the average 2600 given in the table.

The method thus described may also be applied to the stretch of track for which rail depression at the rear wheel load was observed successively at 17 ties for the stretch of track just west of location 4 (see Fig. 63 for the net rail depressions) by substituting for  $y_1$  in equation (9') the individual values of the net rail depression at the rear wheel for  $y_1$ . The values so computed are recorded in Fig. 63 at each tie position. It is seen that the values have considerable variation, though of course the stiffness of the rail masks to a considerable degree the variability in the rail support. The values range from 1800 to 3000 and average 2400. Early in the tests the west portion of this stretch of track was seen to be less regular in play and general variability than in most other places along the track, and accordingly the stretch was chosen for the tie-to-tie load-depression test as track having marked unevenness in rail depression. The "hole" at tie 7 in the right hand portion indicates marked variability in the track.

Calculations of  $u$  have also been made by using the depression values obtained from levels taken on a point on the tie just outside the tie-plate. These values of  $u$  are somewhat larger than those obtained from levels on the rail, as may be expected from their not including the compression or detrusion of tie-plate into tie and because of the slight flexure of tie between rail and tack point. These data are useful in providing a check on the other data.

For the five locations at which track depression at one setting was measured, levels were also taken on both the north and the south rail at two ties between the wheels (the only position on the south rail readily usable for taking sights) in an effort to make some comparison of the stiffness of the track at the two rails. At one of these locations the data were found to be unreliable. For the four other locations the depression of the south rail at these ties was quite variable in comparison with the depression of the north rail just opposite, but the average at the south rail was about 8 per cent more than the average of the corresponding values of the north rail. However, the variability in the conditions along the track from point to point was such that the data are not considered conclusive. Rather it is believed that the stiffness of the track along the south rail was in general greater than that along the north rail, which is away from the other tracks. In the one test in which the load was moved from tie to tie and level readings were taken on the north rail at the rear wheel for every setting, level readings were also taken on the south rail at seven consecutive ties. In these the depression at the south rail averaged slightly greater than that at the north rail.

**38. Stresses and Moments in Rail.**—To get information on the variability of stresses in rail for uniform conditions of static loading, measurements of stresses in the two edges of both the north and the south rail were made immediately under the rear wheel of the heavily loaded car when over the middle of the width of the tie for every other tie at or including four of the five locations on which track depression tests had been made. Measurements of stresses at every tie would have been preferable, but the time available was too limited to permit increasing the testing work. The stretches of track used were considered to be representative of the general condition of the track except that at a point west of location 4 there was a low spot somewhat greater in length than was found elsewhere on the track. In each location is included a rail-joint on one rail for which of course no rail stress was measured.

In making the tests the car was moved from point to point and spotted over the middle of the gage line for which the reading was to be taken. It was found, as determined

by chalked places on the top of the rail, that the wheel bearing on the top of the north rail came at approximately the same place relatively to the width of the head at every test spot along the track and that the same regularity was found in the bearing position on the south rail, though the position on the two rails was not the same, and there was other evidence that the point of application of load by the wheels was essentially the same at all the points of test.

TABLE 22

Observed Stresses at the Two Edges of Base of Rail, Mean Stress, Ratio of Stress at Outer Edge to Mean Stress and Vertical Bending Moment—Locations 1, 3, 4 and 5—130-lb. R.E. Rail—Chesapeake & Ohio Railway

Load is 30,000 lb. on each wheel of four-wheel truck. Stresses are in pounds per square inch and moments in inch-pounds. Analytical moment is 260,000 inch-pounds.

| Location    | Series      | North Rail |            |       |                        |                                    | South Rail |            |       |                        |                                    |        |        |

\*Values at points opposite a rail-joint are not included in the averages.

The stress at the two edges of the base of rail developed with the heavy load and the mean stress in base of rail found by averaging the stresses at the two edges are given in Table 22 for the 30 places on each rail opposite to each other at which the stresses were observed and also the corresponding stresses at 7 places opposite rail-joints of these

stretches of track. The stresses at the outer edge and the inner edge of the base of rail given in Table 22 are plotted in Fig. 70 and 71 and the points are connected by fine full lines and fine dotted lines, respectively, and the mean stress in base of rail is also plotted and the points are connected by the heavy dotted line. The stresses given are for the bottom of the rail as reduced from the values measured at the two gage lines which were located on the upper surface of the rail flange .18 in. inward from the extreme edge and .53 in. above the bottom of the rail. In the reduction process, the mean stress at the level of the two gage lines (average of the observed stresses at the two gage lines) is multiplied by the ratio of the vertical distance between the horizontal geometrical axis of the rail section and the bottom of the rail to the vertical distance from the same axis to the level of the two gage lines (which ratio for the position of gage lines used was 1.21)—the result is the mean stress at the bottom of the rail. Half of the difference between the stresses at the two gage lines is the lateral bending stress at either gage line—positive at one edge and negative at the other. Since for the rail section the lateral bending stress remains the same at any given distance from the vertical axis, the lateral bending stress immediately below a gage line will be the same as that at the gage line. If the edge of the bottom of the rail is farther away from the vertical axis than is the corresponding gage line, a reduction is made by multiplying the given lateral bending stress by the ratio between the respective distances from the vertical axis to the edge of the base and to the gage line (1.06 in this case). This resulting lateral bending stress is then added to the mean stress at bottom of rail or subtracted therefrom to obtain the value of the stress at either edge of base of rail.

The averages of the mean stresses in base of rail developed with the heavy load at the various places at which stresses were measured in the four locations, excluding those opposite a rail-joint, (60 places in all), are given at the bottom of Table 22. The average of the stresses found in the north rail, 11,000 lb. per sq. in., is a little greater than the analytical value 10,200 lb. per sq. in. calculated with the average value of  $u$  (2600) found for the observed net depressions at the north rail. The observed mean stresses in the south rail are smaller than those in the north rail, their average (9700 lb. per sq. in.) being about 10 per cent less. Possibly a firmer condition of the ballast and tie beds at the south side of the track explains part of this difference in stress in the two rails. The ballast between track No. 1 and track No. 2 was fairly full between the tie ends and therefore the tie support at and near a tie end would naturally be firmer than that beyond the north rail where the shoulder sloped off in the way usually found at the outside of a track. However, the rail depressions on the south rail described in Article 37 "Values of Modulus of Elasticity of Rail-Support  $u$ " do not indicate that the support of the south rail is stiffer. Doubtless the differences in stresses are due mostly to the variations in rail support from point to point at the several locations.

Table 23 gives averages of the mean stress in base of rail with heavy load for each of the four locations and the average mean stress for the seven places opposite a rail-joint at these locations. Notwithstanding the great variation in stress from point to point the values of the average mean stress away from a rail-joint for the four locations do not differ greatly. The average of the mean stress opposite a rail-joint for the seven places included in the four locations is 8100 lb. per sq. in. This average is 79 per cent of the average of all the mean stresses away from a rail-joint in these four locations. If all 20 places at which stresses opposite a rail-joint are considered, the average mean stress is 8800 lb. per sq. in., which is 86 per cent of the average of all the mean stresses observed at points away from a rail-joint. As the places away from the four locations include several low stresses in the north rail and high stresses in the south rail, the

values within the four locations seem more likely to be comparable and .79 a more probable ratio than .86. In either event, the stress and the moment developed in rail opposite a rail-joint average considerably smaller than those found at places away from a rail-joint. Here again the difference may be attributed to greater stiffness or less play just opposite a rail-joint than at points adjacent thereto.

Stresses in rail were measured under both heavy and medium loads at points opposite 15 rail-joints (see Table 20). The stresses for the medium load (medium load is one half of heavy load) were not generally closely proportional to the ratio of the loads. At nine places the stresses with the medium load were greater than those corresponding to

the ratio of the loads. At four places the stress ranged from .82 to 1.00 times that developed with the heavy load at the same place. At one place the stress for the medium load was .34 of that with the heavy load. For the light load the stresses were still larger in comparison with those found for the heavy load. As noted in Article 26 it is evident that in places along the track the medium load gave stresses that are large in proportion to the ratio of the loads and at other places smaller stresses, according to the conditions of the individual tie supports at and near the loads.

A characteristic of the data recorded in Fig. 70 and 71 is the marked variation in stress and the quick change in stress from point to point along both the north rail and the south rail. It is seen that the greater stress is sometimes at one edge of the base of rail and sometimes at the other—changing from one side to the other and ranging from nothing at one edge to double the mean stress at the other—at one place showing a compressive stress of 4600 lb. per sq. in. at one edge, and at another place showing a tensile stress of 3000 lb. per sq. in. at the outer edge and 29,000 lb. per sq. in. at the inner edge, the latter stress being about three times the average of the mean stress in rail at all the points of measurement. At another place the stress was 7000 lb. per sq. in. at the inner edge and 25,000 lb. per sq. in. at the outer edge. These differences in stress at the two edges of the base of rail and the changes in position of maximum stresses indicate a constantly changing lateral bending of the rail from point to point, sometimes one way and sometimes the other, and also a marked twisting in the rail. Since the position of the wheel on the rail remained relatively the same for all the settings and since the bearing pressure of the wheel on the rail applied almost identical vertical and lateral loads statically at every spot, it is obvious that the variability and stress must be due mainly to the variations in the nature and position of the rail support given by the tie-plate, tie, and ballast just below the wheel and at the nearby ties in either direction.

The mean stress in base of rail shown by the heavy dotted lines in the figures may be considered as representative of the vertical bending moment developed in the rail from point to point. It will be seen that these mean stresses in base of rail vary greatly from point to point along the track, being at one tie 1.6 times the average stress along the track and at the second tie away only .1 times the average stress. These variations were obtained with the same load applied in the same way. With this great variation in stress and bending moment it is evident that there must be a great variation in the load carried by individual ties and in the position and direction of the supporting reaction applied to the rail by the tie-plate, tie and ballast bed.

As even the maximum stresses in the rail are not large, with a few exceptions, it may not be a question whether the rail is strong enough to take these twisting and lateral bending stresses, even though the effect of the variability of the reaction forces upon the motion of a moving train may be expected to increase the stresses at many points and to cause greater wear of wheels and rails than would be found in track developing greater uniformity in stresses, and though there is in addition the further effect of speed and imperfections of counterbalancing. The effect of the variability upon the tie and ballast bed, moreover, is of serious concern; it is evident that the variability in the direction and amount and distribution of bearing pressure on tie and ballast bed will greatly affect their wear, durability, and maintenance, and will have a great influence on the quality of the track surface and the cost of its maintenance.

The values of the vertical bending moment in both north rail and south rail are given in Table 22. The values are calculated from the mean stress in base of rail and are, of course, proportional to these stresses. It will be noted that the variation in the moments is very marked. It will be seen, too, that the moments in these two rails at

points opposite each other are sometimes alike and sometimes differ greatly. The highest values are 412,000 in.-lb. in the north rail and 437,000 in.-lb. in the south rail at points opposite each other, the latter being 1.8 times the average value at points on the same rail not opposite a rail-joint. At one point the moment in the north rail is 297,000 in.-lb. and in the south rail just opposite 146,000 in.-lb. The smallest value observed is 19,000 in.-lb.—here the stress in the outer edge is 6000 lb. per sq. in. tension and the inner edge is in compression. In Fig. 72 the magnitude of the vertical bending moments is plotted to scale in the order of the place in track for the four locations. In various ways the variability is striking.

In Table 22 is also given for both rails the ratio between stress at outer edge of base of rail and mean stress in base of rail. When the ratio is greater than 1, the lateral bending of the rail is outward from the center of the track; when less than 1, the lateral bending is inward. It will be seen that these ratios vary widely and quite irregularly.

The magnitude of the lateral bending moment in the rail may be calculated from the excess or deficiency of stress at the outer or inner edge of base of rail as compared with the mean stress in base of rail. The values so calculated for the north rail and the south rail have been plotted in Fig. 73. The outward lines represent values of the lateral bending moment when the rail bends outward from the center of the track and inward lines values when the rail bends inward. The values are plotted in the order in the track for the four locations previously described. In making comparison of the magnitudes of lateral bending moments with vertical bending moments it should be kept in mind that for the rail used the section modulus with respect to a vertical axis is .188 times that with respect to a horizontal axis. The greatest lateral bending moments measured are 41,000, 40,000, 62,000, 43,000, and 38,000 in.-lb. The highest lateral bending stress was 13,000 lb. per sq. in. and this together with the vertical bending stress of 16,000 lb. per sq. in. makes the stress at the inner edge of base of rail 29,000 lb. per sq. in., as compared with the average mean stress in base of rail for all locations on the south rail of 9700 lb. per sq. in. In considering these lateral bending stresses and lateral bending moments it should be remembered that the method of static loading used did not include application of the lateral forces that may result from lateral swing or side thrust of locomotives and cars.

The direction of the lateral bending of the rail is of some interest. The summary of the direction of lateral bending given in Table 24 shows that for the 30 places of measurement each rail bent outward at 11 places and inward at 19 places. For the different combinations of lateral bending in the two rails at points directly opposite each other, the north rail bent outward and the south rail inward in seven places, outward and outward in four places, inward and outward in six places, and inward and inward in 13 places. Except for the differences in cant of the two rails, it is thought that the principal sources of the variations in lateral bending outwardly or inwardly are differences in conditions of rail support at and near the point of measurement, much of which is due to irregularities of tie-plate bearing.

With reference to cant of rail, the data of the tests show that although the inclination of the tie-plates was 1 in 28, the average measured cant of the unloaded north rail for 63 points at and near the various test locations was 1 in 27 and for 63 points of the unloaded south rail 1 in 16, the cant for each rail being fairly uniform throughout. The larger cant in the south rail may have been the main reason the wheel flange held close to the south rail in moving along the track, but it seems not to be a dominating influence in giving direction to the lateral bending. This canted rail has more points

Fig. 72.—VERTICAL BENDING MOMENT IN NORTH RAIL AND SOUTH RAIL AT THE REAR WHEEL WHEN THE LOAD IS MOVED FROM POINT TO POINT—LOCATIONS 1, 3, 4 AND 5—TESTS ON CHESAPEAKE AND OHIO RAILWAY.

Fig. 73.—LATERAL BENDING MOMENT IN NORTH RAIL AND SOUTH RAIL AT THE REAR WHEEL WHEN THE LOAD IS MOVED FROM POINT TO POINT—LOCATIONS 1, 3, 4 AND 5—TESTS ON CHESAPEAKE AND OHIO RAILWAY.

of inward bending than outward bending and the average of the stresses at the inner edge of base of rail is greater than that at the outer edge, while tests of track with rail not canted have given more cases of outward bending than inward and greater average stress at outer edge than at inner edge.

## VI. TESTS OF GEO TRACK ON THE MISSOURI PACIFIC RAILROAD

39. **Description of the GEO Track.**—The tests were made on the Missouri Division of the Missouri Pacific Railroad (on the line frequently called the Iron Mountain Route) at Middlebrook, Missouri 83 miles south of St. Louis, in October 1931. A stretch of GEO track about five and one-half miles long extending each way from Middlebrook was laid in December 1930. This is one of four locations on which this form of construction had been built by the Missouri Pacific Railroad.

Fig. 74.—VIEW OF RAIL, TIE-PLATE, TIE AND FASTENINGS—110-LB. R.E. RAIL—GEO CONSTRUCTION ON MISSOURI PACIFIC RAILROAD AT MIDDLEBROOK, MISSOURI.

The main features of the installation of GEO track at Middlebrook may be described as follows (see Fig. 74). A heavy and stiff tie-plate having two heavy ribs or shoulders placed so that the base of rail closely fits in between is securely fastened to the tie by four screw spikes. On each side of the rail the outer leg of a U-shaped clamp rests upon the tie-plate outside the rib and a shorter and inner leg rests on the base of rail; a clamp bolt with its head lying in the slot of the rib at the middle of its length and reacting against the bearing face at the top of the slot has its nut tightened to hold the base of rail closely against the tie-plate. A coil spring washer was used under the nut of the clamp bolt. A creosoted poplar shim, compressed in its fabrication from a thickness of about .4 in. to about .2 in., and nearly filling the width between the ribs of the tie-plate and having a length greater than the width of the tie-plate lies on the tie-plate

and under the rail. In this installation the ties were preadzed and prebored by machines to receive the tie-plates and screw spikes; the tie-plates were fastened to the ties in the plant by a power wrench that applied a uniform torque to the screw spikes. The boring and adzing were such that the track gage and the cant of the rail, when the ties were placed in track and the rails laid on them, were not modified in the track-laying process. The application of the tie-plates in the shop in advance of track laying results in insuring more accurate fitting of tie-plate on ties and in providing more nearly uniform surface bearing of tie-plate on tie and in securing the desired cant of rail and uniformity of conditions from tie to tie along the track. Another advantage lies in that the tie-plate bearings at the two ends of the tie by the method of adzing are held in the same plane or in planes corresponding to the desired cant. At the same time the cant of the rail is kept the same in both rails throughout the length of track. In fact, except for the Delaware, Lackawanna and Western Railroad this track is the only track so far tested in which the specified cant (in this track, 1 in 40) remained closely uniform throughout. In this installation a special joint tie-plate  $27\frac{1}{4}$  in. long extended over the two ties of a suspended joint, and the rail clamps and clamp bolts were placed at the side of the middle of the width of the ties next to the rail end.

The test locations were on fills of 4 to 8 feet, about seventy years old and wide, solid, and substantial. At the three test locations one and a half miles north of Middlebrook the ballast was hard, broken limestone free from fine particles and generally ranging from 1 in. to 2 in. in size. The ballast bed at these locations was unusually stiff. At the three locations one-quarter mile south of Middlebrook the ballast was flint gravel. It ranged from  $\frac{3}{4}$  in. down and the sample examined contained 37 per cent of particles smaller than  $\frac{1}{4}$  in. The limestone ballast well filled the spaces between the ties out nearly to their ends and the shoulders were wide and full. The flint ballast also was full between the rails, but the shoulders and slope were not so full.

The ties were treated oak ties (sizes 4 and 5 of standard sizes of American Standards Association), nominally 7 in. by 9 in. by 8 ft. The ties were unusually straight and uniform and well graded in size. Of 102 ties measured at test locations, 62 per cent had a width between 9 and  $9\frac{3}{4}$  in., 22 per cent between 8 and  $8\frac{3}{4}$  in., and 10 per cent between 10 and  $10\frac{3}{4}$  in.—the remaining 6 per cent were narrower than 8 in. The spacing of the ties was unusually uniform. Away from the four ties at a rail-joint, of 128 ties measured 21 per cent were between 20 and  $20\frac{3}{4}$  in. center to center, 32 per cent between 21 and  $21\frac{3}{4}$  in., 30 per cent between 22 and  $22\frac{3}{4}$  in., and 12 per cent between 23 and  $23\frac{3}{4}$  in., the average spacing being  $21\frac{1}{2}$  in. The general spacing between the four ties at a rail-joint was 19 to  $19\frac{3}{4}$  in.

The rail was 110-lb. R.E. laid in December 1930. The tie-plates were 7 by 14 in., with an inclination of 1 in 40 and no eccentricity.

The track in general was in excellent condition. It is reported that no maintenance work had been done upon it during the year it had been in service. The road is used principally for passenger service and not many freight trains are run over it, the heavy freight traffic being carried by another line.

40. **Method of Testing.**—Steel hopper coal cars of 70-ton capacity were used in the test. Two loads were used—(1) an unloaded car, (2) a car heavily loaded with coal. The loads on one end of the car were 26,200 lb. for the light load, and 105,400 lb. for the heavy load, which have been called 6500 lb. per wheel for the light load, and 26,500 lb. for the heavy load. For any test a rear wheel was spotted at the desired point midway between two ties (the rail fastening preventing measurement over a tie),

and the car was then moved successively from point to point along the rail. The stresses in rail were measured at the two edges of base of rail at gage lines  $\frac{1}{4}$  in. above the bottom of the rail by means of a Berry strain gage of 2 in. gage length.\* The Berry strain gage was used by a skillful and experienced operator and it is believed that the individual readings are generally accurate within 500 lb. per sq. in. Two engineer's levels and a special level rod 6 in. long graduated to one-hundredth inch and generally read to half-hundredths were used in getting the vertical movement between rail and tie-plate, tie-plate and tie, rail depression, and for other purposes. It is believed that under the conditions of the work these levels were accurate to one-hundredth inch. The readings of strain gage, levels, etc., were generally taken (1) at zero load (before the load was applied), (2) with the load in place, and (3) with the load removed (zero load).

41. **Tests of Track Depression.**—The method of determining the track depression involved taking levels along the track (1) with the track in an unloaded condition, (2) with the light car used as the load, (3) with a heavy car used as the load, and (4) again in an unloaded condition. The levels were taken with the pointed end of the special level rod (described elsewhere) placed in a punch mark on the base of the east rail near its outer edge over the middle of the width of each tie and in a punch mark on a nail in the tie about 1 in. away from the outer edge of the east tie-plate. For each test location these levels were taken at each individual tie from a position beyond the middle of the length of the test car to a tie about 17 ft. behind the rear wheel of the rear truck. Two engineer's levels were used, one opposite the front wheel of the rear truck and the other at a point of 10 ft. behind the rear wheel, each instrument being about 10 ft. from the rail. Check readings were taken on nearby benchmarks. To insure accuracy a second man is kept at the instrument to watch the level bubble. Levels on punch marks on a few tie-plates near the wheels of the rear truck were also taken.

To find the total vertical movement between the west rail and a nail on the tie about 1 in. beyond the outer edge of the tie-plate, for use in a comparison of the vertical movement of the two rails, a wooden bar placed over the top of the two rails carried at its west end an Ames dial having a plunger which rested on the nail in the tie; the difference in readings in the unloaded and the loaded conditions gave the value of the relative vertical movement between the west rail and the tie.

From the tests of track made previously, it is to be expected that the gross depression of rail caused by the application of a light load may be greater proportionally than that of a heavier load and that the added depression of the heavy load will in general be approximately proportional to the difference in the two loads. It is also to be expected that part of the depression found with a light load will be due to play existing between rail and ballast bed and hence should not be considered in determining the stiffness of the track.

In Fig. 75 and 76 the results of the gross depression measurements of rail and tie for light and heavy load for the six locations at which levels were taken are plotted as ordinates at each tie including seven ties at each end away from the two wheels of the car truck, and for convenience these points are connected by lines. The points on the dashed line at the upper part of each diagram (named the derived play curve) represent the play between the rail and the tie bed as found by subtracting from the gross depression with the light load a quantity found by multiplying the excess of the gross depression with the heavy load over that with the light load by the ratio that the excess of

weight of the heavy load over that of the light load bears to the weight of the light load. This calculation is based on the assumption that the light load has brought both rail and tie to a firm bearing at each tie and that the further depression made by the heavy load is everywhere proportional to the added load taken by individual ties. It is possible that the light load may not have fully seated all the ties on the ballast bed, but except at ties near the end of the depression curve the ties adjacent to such unseated ties may take more than their share of load so that the average value of the rail depressions will not vary far from being representative of the average individual tie loads. At and near the ends of the depression curve the ties may not have taken much load, and in calculations their depressions may well be omitted from consideration. It should also be noted that upward movement of the rail and tie will not be representative of actual negative vertical pressures acting on the rail, as is discussed in Chapter V.

**42. Elements in the Total Rail Depression.**—The vertical movement between the rail and the tie's bed in the ballast may be considered to be made up of (a) play between rail and tie-plate, including any compression of the wooden shim by the applied load, (b) play between tie-plate and tie including any vertical movement of tie-plate due to imperfect bearing of tie-plate on the adzed surface, (c) compression of the tie throughout its depth when load is applied through the tie-plate, and (d) play between bottom of tie and its ballast bed including any bending of the tie to reach the bed directly under the rail. Below the tie, there will be a vertical depression of the ballast and roadway, which of course will vary according to materials and conditions. No comprehensive tests were made to determine precisely the value of the several parts referred to, but the following statements give an idea of the distributions of the vertical movements as judged from the measurements and observations made in the field.

(a) The compression of the wooden shim (which in its fabrication was compressed to half its original thickness) is minute—probably less than can be told with the scale of the measurements taken; its usefulness may be expected to be due principally in overcoming roughnesses of metallic surfaces and in avoiding movement of metal on metal, with perhaps some resulting adjustment in the bearing from side to side of rail base by differences or changes in thickness of the shim at the two edges with time. The total vertical movement between rail and tie-plate was generally hardly measurable, probably usually less than .01 in. In 28 places measured in four test locations, the play between rail and tie-plate, as found after the heavy load was applied, was approximately .01 in. at 3 ties, .02 in. at 5 ties, and .03 in. at 1 tie. This freedom from much vertical movement between rail and tie-plate is to be expected with the form of rail clamp used. It was observed that rail clamps were slightly loose at two ties on the test locations.

(b) The play between tie-plate and tie was also generally very small. At 4 ties out of 28 a play of .02 in. was observed at the east rail on the application of the heavy load and a play of .01 in. at 4 ties. On the west rail, at the same test locations, the vertical movement between rail and tie, as measured by a dial gage, was .02 in. or more at 6 ties out of 38. It was evident that the method of preadzing employed and also the method of holding the tie-plate against the tie with screw spikes generally resulted in full bearing and lack of play at most of the places where measurements were made. In a few ties away from the test locations used, imperfect tie-plate bearings were found for part of the length of a tie-plate and a thickness of paper could be inserted under the tie-plate for a few inches or the edge of a shovel for a short distance. Altogether, however, the tie-plate bearings were far superior to the usual conditions found with ordinary track spiking or even with the best driven spiking of tie-plate to tie.

(c) Little definite information is known on the amount of elastic compression produced in the tie through its depth by the tension retained in the screw spikes after a period of time and the consequent reduction in the amount that the tie would otherwise be compressed when its load was applied. It seems probable that part of the original squeezing of the tie when the screw spikes were applied at the fabricating plant had been lost and the elastic part that remains will vary from tie to tie. Perhaps the average compression upon application of the test load, judging from a few laboratory tests, was of the order of .01 in. or .02 in.

(d) As reported elsewhere the play between tie and ballast bed ranged from 0 to .14 in. The total play or looseness between rail and tie-plate, tie-plate and tie, and tie and ballast bed ranged from .01 to .16 in. These values do not include the amount the tie is compressed by an applied load.

**43. Vertical Play or Looseness between Tie and Ballast Bed.**—One of the purposes of the tests was to learn what vertical play or looseness may exist between tie and ballast bed at individual ties, both when the rail clamp is fastened and when the fastening is released; that is, to determine whether there were "hanging" or "suspended" ties or whether all ties remain on their ballast bed when the rail is in an unloaded condition. The method used was to take levels accurately on a nail inserted in the tie about 1 in. away from outer edge of the tie-plate, as heretofore described. The level readings were generally made at the east rail only, though in some cases readings were taken at both ends of the tie.

The first readings were taken with the rail clamp fastened with its original tightness. The two rail clamps at one end of the tie were then loosened and level readings taken on the nail. A bar was then placed under the rail head and over a fulcrum block resting on the tie beyond the gage side of the rail and downward pressure was exerted by a man at the end of the bar. The resulting pressure on the tie (probably between 500 and 1000 lb.) was sufficient to seat the one end of the tie on its ballast bed or at any rate to hold it very nearly at that position. Level readings were again taken. It was found from other measurements that the fastening of rail to tie-plate at the further end of the same tie was not rigid enough to affect the movement of the tie at the test end. This was evidenced by results obtained on certain ties by also loosening the rail clamps at both ends of the tie. The foregoing test is termed the push-down test.

Following the push-down test the pull-up test was made by inserting the bar through ballast under the end of the tie, using a short block as a fulcrum, and applying suitable pressure at the further end of the pry. Pressure was exerted at the end of the pry until the rail and tie-plate and rail were surely in contact, and level readings were again taken on the tack 1 in. outside the tie-plate. Any difference between the level reading referred to and the one taken before the rail clamp was released would indicate a movement between tie and rail. Of course a lift of the rail would be detected by a decreased level reading.

It was found in most cases that upon loosening the rail clamps and releasing their hold the tie dropped somewhat until it was supported at some place on the ballast bed. In Table 25 are given in the fourth column the amount of the drop of the tie upon release of the rail clamps at test locations 1, 2, 3 and 4. Observations were made by push-down tests on 35 ties at the test locations used. In 10 ties no vertical movement of the tie was observed upon release of the fastening, 11 ties

dropped .01 or .02 in., 6 ties dropped .03 to .05 in., 6 ties dropped .06 to .09 in., and 2 ties dropped .10 in.; 14 of the 35 ties then showed a play between .03 and .10 in. It is apparent then that many of the ties may be classed as "hanging" ties and that for these ties and the stiff ballast support the rail in many cases must depress an

|               |                                | 11         | .02                                  | .02                        |
|               |                                | 1          | .00                                  | .00                        |

amount equal to a considerable proportion of the net depression of the track before individual tie bearings will permit loads to be carried by such ties. It may be noted that there appears to be little difference in the proportional number of ties having the different ranges of drop with the two kinds of ballast for the locations on which observations were made.

The push-down test at the same ties, made after the rail clamps were loosened, indicated whether the tie had reached its normal bearing bed before the push-down test was applied. In the last column of Table 25 is given the total movement of the tie including the drop and the push-down movement. For about 40 per cent

of the ties tested no further vertical movement of the tie was found on application of the push-down test; these ties had already dropped to the bearing bed. The other ties were forced down a small distance, usually .01 or .02 in., but sometimes .04 or .05 in. The greatest value of drop plus push-down was .14 in. In general, however, the releasing of the rail clamps permitted the tie to assume its normal bearing bed or to come within a small distance of it.

The pull-up test, as generally carried out, showed the relative position of the tie with respect to the rail after the push-down and pull-up tests had been applied and in some respects was a check on the observations. In 26 out of 35 ties the results indicated that the tie came back to its original position with respect to the rail or closer or that the rail was lifted slightly. In 8 of the 35 ties the pressure applied did not bring the tie within .01 in. of the original height; 1 tie remained .02 in. low. In these few cases either the lifting of the tie was obstructed or some slight inaccuracy developed.

The ties included in the push-down and pull-up tests were chosen at the locations where stresses in rail had been measured and load depression tests made. Time was not available to make observation on all ties in the test locations.

In Table 26 is recorded the vertical play or looseness for ties 10 and 11 at location 4 (flint ballast) — two hanging ties. For these ties the rail clamp on one rail was first loosened and level observations made at the tack outside of each rail and at the tack at the middle of the length of the tie, and observations were also made with the rail clamps on both rails loosened. The observations were made after the tie was free to drop and also after the push-down test had been applied. The greatest amount of drop for tie 10 with clamps of both rails loosened was .05 and .10 in. for the two end points and .05 in. for the middle point, and for tie 11, .05 and .07 in. for the two end points and .05 in. for the middle. It is seen that both ties were hanging ties. It is apparent from the data that the two ties tilted or rocked about their middle when pressure was applied at either end of the tie and that the ties were center-bound.

There were further evidences that the tie bearings partake of the center-bound condition in the locations on flint ballast. For four consecutive ties which came at or between the two wheels of the end truck of the loaded car when the load depression test had been made at location 5, the depression at nails inserted in the extreme end of the tie was greater than the depression of the nail close to the outer edge of the tie-plate by .005, .015, .01, .025 in., respectively. On all locations on the flint ballast (see Fig. 76) the depression of the tie in the static load tests was in general greater just outward from the tie-plate than those measured at the rail. Other observations also indicated that many ties were in a center-bound condition and that the part of the ties outside of the rails did not transmit to the ballast its full share of the tie load and that there was evidence of looseness at the tie end.

**44. Variation in Load Taken by Individual Ties.**—In Fig. 75 and 76 is also plotted the derived play curve of the rail with respect to the ballast bed found on the assumption that the light load seats the tie on its ballast bed except near the ends of the depression curve and that the net depressions of the light and the heavy loads are proportional to their weights. The values of the derived rail play with respect to the ballast bed in the case of the limestone ballast, throughout the length of the depression curve on which the tie may be expected to be brought down to full ballast bed bearing by the light load, as recorded in the figures, ranged from 0 to

TABLE 26

**Vertical Play or Looseness between Tie and Ballast Bed at Two Ties at Location 4 on Flint Ballast—Tests on Missouri Pacific Railroad at Middlebrook, Missouri**

Values are given in inches.

| Condition of Rail Clamps               | Condition of Tie               | Vertical Drop of Tie |              |            |

|                                        | Push-down applied at east rail | .04                  | .05          | .07        |

.06 in. It will be seen from an examination of the diagrams that there is considerable variation in the amount of this play between rail and ballast bed at different ties in the same vicinity. For example, for location 2 at ties 3 and 4 there is little play, while at ties 11 and 1 the play indicated by the levels is .06 in. Further, in the case of location 2, where the drop of tie found when the rail clamps were loosened had total values at ties 11 and 1 of .11 and .10 in. (see Table 25), it is evident that ties 11 and 1 under the heavy car must be taking no more than 30 and 50 per cent of the proportionate share of the load that would be expected to be carried by them. Besides, it is obvious that this deficiency in the vertical support (or upward pressure) given by these ties will result in increased stresses in the rail in the neighborhood of ties 11 and 1, as is pointed out in the discussion of the stresses along the rail for location 2. Conversely, considering the lack of play at ties 2, 3, and 4 which lie between the two adjacent spots (that is, between ties 11 and 1, and ties 5 and 6), by similar reasoning from the play and the drop observed the upward pressure taken by these three ties (11, 1 and 5) is roughly 30, 50 and 20 per cent of their proportionate share, respectively, so that ties 2, 3 and 4 carry perhaps twice the share they would carry if the ties had uniform supporting value, and

consequently the moments and stresses developed at ties 3 and 4 (spot J) were only about 40 per cent of normal value, as is seen from the data of stress measurements given elsewhere. Similarly at location 1 at ties 3 and 4 the play between rail and tie bed is 0, while at ties 10 and 11 the play is .04 in. Variations in tie load must result at ties in the neighborhood of ties 10 and 11, just referred to, where the drop of tie when the rail clamps were released was .05 and .08 in., these values being greater than the ordinate of the derived play curve.

In the case of the flint ballast, at location 4 the derived play curve of the rail with respect to the ballast bed was quite uniform, the ordinate being about .05 in. through most of the central portion of the length of the depression curve. At ties 10, 11 and 1 at the right side of the diagram the tie drops upon loosening the rail clamps were .07, .07, and .07 in.; these values are greater than the total rail depression at these ties for the heavy load and hence they carried no load. If the wheels had been directly over or near these ties they would probably have carried 80 per cent of their calculated share of load. In location 5 the derived play was fairly uniform, about .03 to .05 in. The rail clamps were not loosened, but the greater total net depression in the vicinity of ties 6 and 7 (see Fig. 76) indicates that ties 6 and 7 would have given large drops and that these two ties did not take their share of load. At location 6 the vertical play of the rail was very small, in general 0 or .01 in. Although tie drops were not taken it is probable that there was a fairly proportional distribution of load among the ties as compared with the other locations.

45. **Values of Modulus of Elasticity of Rail-Support  $u$ .**—The meaning of the term modulus of elasticity of rail-support  $u$  and the method of computation of values derived from data from tests have been discussed in Article 37 "Values of Modulus of Elasticity of Rail-Support  $u$ " for the tests on the Chesapeake and Ohio Railway. The method used for determining  $u$  from the tests on the Missouri Pacific Railroad is the same except that data for pull-up and push-down tests are not generally available for the stretches along the test locations on which load-depression tests were made. For the main part of the depression curve between wheels and next to them, as in the Chesapeake and Ohio Railway tests, the rail net depression curve for the heavy load may be expected to represent the average vertical resistance to downward movement (tie load proportional to the ordinate). If at any tie along this length the light load did not bring the tie to a fair bearing on the ballast bed, another tie or ties will usually have carried a greater proportion of load to make up for the discrepancy. For a short distance at the ends of the net depression curves a small estimated allowance for the effect of play (in this case mostly between tie and ballast) has been made for the ties that obviously have not carried full load.

In Fig. 77 the rail net depression ordinates for the six locations, obtained by subtracting from the ordinate of the gross rail depression curve for the heavy load the corresponding ordinate for the derived play curve, have been plotted for the ties that are considered to carry load. Beyond these ties light dotted lines connect ties that are not considered to carry full proportionate load. The rail depression at the individual ties found from the ordinates of the net depression curve may then be summed for the length referred to. The value of the modulus  $u$  is then calculated by dividing the total weight on the two wheels of one rail by the product of the average tie spacing and the sum of the net rail depression at each tie so found. Table 27 gives in one column the values

Fig. 77.—RAIL NET DEPRESSION ORDINATES FOR LIGHT AND HEAVY LOADS AT LOCATIONS 1, 2 AND 3 (LIMESTONE BALLAST) AND LOCATIONS 4, 5 AND 6 (FLINT BALLAST)—TESTS ON MISSOURI PACIFIC RAILROAD.

of the modulus  $u$  for the three test locations on limestone ballast and the three on flint ballast by the method that uses the summation of net rail depression ordinates. The values on the limestone ballast (3700, 5500, 6200, average 5100) are extremely large and represent a very high stiffness in the track. The modulus for the track on flint ballast (2500, 2600, 3600, average 2900) showed a less stiff track but the values of  $u$  are still quite high.

A striking feature of the track depression tests on the limestone ballast, then, is the small value of the net track depression and the consequent high stiffness of the rail support and the correspondingly large value of the modulus of elasticity of rail support found. At location 1 the net depression of the rail at the ties between the wheels and just outside for the heavy load averaged .09 in., the value being given to the closest hundredth. For location 2 the net depression for the corresponding ties was .06 in., and for location 3, .05 in. These are extremely small net track depressions for a load of 26,500 lb. on each wheel of a four-wheel truck.

For the track on flint ballast the net depression of the rail at the ties between the wheels and just outside averaged .12 in. for location 4, .12 in. for location 5, and .09 in. for location 6. These may be compared with net rail depressions under similar loading reported in the First Progress Report for track on the Illinois Central Railroad having limestone ballast, which ranged from .20 to .40 in. and gave an average value of  $u$  of 1200.

It is apparent that the fastening of the tie-plate to the tie in a manner that largely retains the initial compression of the tie decreases the compression of the tie itself occurring when a wheel load is applied. This is evidently one source of the greater stiffness found on both the limestone ballast and the flint ballast in comparison with that observed on track not having the tie-plates so fastened to the tie.

It is apparent that with the stiff support given by the substructure on the limestone ballast (by far the stiffest track yet tested by the test party) seemingly small variations in conditions from point to point produce hard spots and less stiff spots that result in unevenness in net track depression which has a considerable effect on the uniformity of the track surface. It would appear, too, that the hard spots in this ballast will not be pounded down much under heavy traffic as compared with the change in elevation produced on the less stiff spots. It is evident, then, that for such ballast methods of spreading and tamping should be devised and employed to produce a more uniform stiffness of support along the track than is frequently or generally obtained. This matter is discussed further in Chapter VIII.

In the case of the flint ballast (which was more regularly graded from the fine to the larger particles and had considerable fines but no particles larger than  $\frac{3}{4}$  in. and in which many of the particles above  $\frac{1}{2}$  in. could easily be broken into smaller particles) tamping was more easily done and uniformity of play and bearing on ballast could be more easily attained, though, of course, it is to be expected that this ballast will not withstand heavy traffic as will the broken stone ballast used in the other test locations. The lesser stiffness of the flint ballast layer because of the amount and nature of the fine material, resulting in greater track depression and in a smaller value of  $u$ , permits greater variation in play from tie to tie without resulting in a relatively higher variation in stress in rail found with the high stiffness of the limestone ballast. The relative resistance of the two ballasts to retention of track surface under heavy traffic with time

is another question. It is to be expected, of course, that the limestone ballast will better stand the test of heavy traffic. The source of the difference in stiffness and ease of tamping need not be taken up here. In the flint ballast, the end of the ties appeared less well supported than was the case with the limestone ballast, and there was an appearance of pushing out or shaking down of the flint ballast beyond the ends of the ties and at their edges (which might contribute to a center-bound tie condition) although the shoulders were wide and full all along the track.

A further comment on effects of play on the quality of track may be made. The play between rail and ballast bed at location 3 on the limestone ballast for 6 ties at and near the wheels averaged about .05 in. and was quite regular in amount. It would seem that the corresponding value of  $u$  (6200) is probably representative of the value of  $u$  on the limestone ballast when the play is uniform along the length of the wheel base and the drop of tie on release of rail clamps is small. At location 2 the value 5500 assumes that all the ties except at the ends of the depression curve have taken their proportional share of load. The value at location 1 (3700) although smaller shows very stiff track. The average value of the modulus for the three locations (5100) indicates extremely stiff track, by far the stiffest yet tested. On the flint ballast, location 6 was quite stiff but locations 4 and 5 although stiffer than most track were lower in stiffness. The average value for the three tests on flint ballast is 2900. The values 5100 and 2900 may be considered to represent the relative stiffness on the two kinds of ballast on this track.

It may be of interest to call attention to the comparative values of the net track depression at the wheels of these heavily loaded cars corresponding to the moduli just given. For the limestone ballast the value of  $y_1$  (rail depression under one of the four wheels of a truck carrying 106,000 lb.) for a modulus of 5100 is .08 in. and for 2900 is .13 in. When the track depression is so very small, it is apparent that the presence of uneven play among the ties and especially the presence of tie drops that will result in uneven distribution of load on nearby ties, if such play and unevenness exists in the track, may have an extreme effect on stress variation in rail from tie to tie and that the effect of variation in play and stiffness will be very marked in very stiff ballast. In other words in very stiffly ballasted track there is a greatly increased need of uniformity of track support, with the alternative of greatly increased variability in stresses and great variations in tie pressures from point to point along the track.

It should be noted that if  $u$  were calculated from gross rail depression the values would be 25 to 40 per cent smaller than those given in the table. As the play involved in the gross depressions furnishes no appreciable resistance to load, values calculated from them should not be considered when  $u$  is to be used in calculating analytical stresses and depressions.

In the last column of Table 27 are given values of  $u$  calculated from the average net rail depression at the two wheels on one rail by the use of equation (9') (see Article 37). For the conditions of these tests the values of  $k$  are smaller than for the tests on the Chesapeake and Ohio Railway. The calculated values of  $k$  for these tests vary from 1.20 for a value of  $u$  at and near 3000 to 1.05 for a value at and near 6400. As in the tests on the Chesapeake and Ohio Railway, the values obtained by this approximate method are larger than are found from the summation of net rail depressions. For the very stiff track the influence of a second wheel on the rail depression at a first wheel is small, and

also the measured depression outside of the two wheels is relatively greater than the analytical value as compared with the differences in less stiff track, so that it may be said that the stiffer the rail support the greater the difference in the values found by the two methods. This is shown by the results in the last column of Table 27.

TABLE 27

**Modulus of Elasticity of Rail-Support  $u$ —Tests on Missouri Pacific Railroad at Middlebrook, Missouri**

The values of  $u$  are given in pounds per inch per inch of one rail. The load was 26,500 lb. on each wheel.

| Average  |           | 2900                                                  | 3400                                             |

46. **Stresses and Moments in Rail.**—To get information on the variability of stresses in rail along the track, measurements of stresses in both the east and west rail were made at the two edges of the base of rail immediately under the rear wheel of the heavily loaded car (26,500 lb. per wheel) with this wheel at the mid-point between ties for points located at every other tie spacing for three locations on the limestone ballast and one location on the flint ballast. Lack of time prevented taking measurements at every tie space and at the two other locations on the flint ballast. The stretches of track used were considered to be representative of the general condition of the track. In each location was included a rail-joint on one rail for which of course no rail stress was measured.

In making the tests the car was moved slowly from point to point and spotted over the middle of the gage line for which the reading was to be taken. Observations showed that the wheel bearing at the top of the east rail came at the same place relatively to the width of the head at every test spot along the track and that the same regularity was found in the bearing position on the west rail, though the position on the two rails was not the same, and there was other evidence that the point of application of load by the wheels was essentially the same at all the points of test.

The stress at the two edges of the base of rail developed with the heavy load and the mean stress in base of rail found by averaging the stresses at the two edges are given in

TABLE 28

Observed Stresses at the Two Edges of Base of Rail, Mean Stress, Ratio of Stress at Outer Edge to Mean Stress, and Vertical Bending Moment—Locations 1, 2 and 3 Limestone Ballast, Location 4 Flint Ballast—110-lb. R.E. Rail—Missouri Pacific Railroad

Load is 26,500 lb. on each wheel of four-wheel truck. Stresses are in pounds per square inch and moments in inch-pounds. Analytical moment for limestone ballast is 185,000 in.-lb. and for flint ballast 208,000 in.-lb.

| Location | Series     | East Rail  |            |       |                  |                         | West Rail  |            |       |                  |                         |

\*Values at points opposite a rail-joint are not included in the averages.

Table 28 for the 24 places on each rail opposite to one another at which the stresses were observed and also the corresponding stresses at 4 places opposite rail-joints of these stretches of track. The stresses at the outer edge and the inner edge of the base of rail given in Table 28 are plotted in Fig. 78 and 79 and the points are connected by fine full lines and fine dotted lines, respectively, and the mean stress in base of rail is also plotted and the points are connected by the heavy dotted lines. Although the stresses were measured at gage lines .25 in. above the bottom of the rail the values have been reduced to a position in the plane of the bottom of the rail by the method described in Article 38.

The values of the mean stress in base of rail from point to point along the track are fairly uniform except for a few places at which quite low stresses were found. Six values of the mean stress on locations 1, 2, and 3 (limestone ballast) ranged from 3600.

Fig. 78.—STRESSES AT OUTER EDGE AND INNER EDGE AND MEAN STRESS IN BASE OF RAIL AT THE REAR WHEEL WHEN THE LOAD IS MOVED FROM POINT TO POINT—LOCATIONS 1 AND 2 (LIMESTONE BALLAST)—TESTS ON MISSOURI PACIFIC RAILROAD.

Fig. 79.—STRESSES AT OUTER EDGE AND INNER EDGE AND MEAN STRESS IN BASE OF RAIL AT THE REAR WHEEL WHEN THE LOAD IS MOVED FROM POINT TO POINT—LOCATION 3 (LIMESTONE BALLAST) AND LOCATION 4 (FLINT BALLAST)—TESTS ON MISSOURI PACIFIC RAILROAD.

to 5600 lb. per sq. in. These low values were found at places where the two ties adjacent to the wheel had little play and little drop (probably .02 in. or less) and the rail and tie support was very stiff, and where for two or three ties beyond each way there was considerable play or drop (.06 in. or more), thus making a condition such that the two ties adjacent to the load take a proportion of the load much larger than the normal share, while the ties farther away take much less load than the normal share found with ties having uniform supporting values. These conditions combined to make the stresses and bending moment in the rail under the load at these points much less than would be developed with uniform tie support. For locations 1, 2 and 3 the average of the mean stresses in base of rail (not including the stresses in rail opposite a rail-joint) is 7300 lb. per sq. in. for the east rail and 8200 lb. per sq. in. for the west rail. Omitting the six low values referred to above, the average of the mean stresses for locations 1, 2 and 3 are 8200 lb. per sq. in. for the east rail and 8400 lb. per sq. in. for the west rail, making an average value of the mean stress for both rails 8300 lb. per sq. in. This average stress is smaller than the analytical value 9200 lb. per sq. in. calculated with the average value of  $u$  (5100) found for the observed net depressions at the east rail. For location 4 (flint ballast) the average of the mean stresses in the east rail is 8900 lb. per sq. in. and for the west rail 9100 lb. per sq. in.—making an average for both rails of 9000 lb. per sq. in. This average value is smaller than the analytical value of 10,300 lb. per sq. in. obtained by the use of  $u$  of 2900 determined from the observed net depressions at the east rail. It may be added that, except for the six low values heretofore referred to, the mean stresses in base of rail at most of the places in locations 1, 2 and 3 do not vary greatly from the average mean stress. For the remaining 30 places at which measurements were made, five places gave values 36, 35, 29, 26 and 25 per cent. greater than the average mean stress (8300 lb. per sq. in.) and two 26 and 25 per cent. less than the average. For the other 23 places the average variation from the average value of the mean stress was 13 per cent. The mean stresses in location 4 are still closer to their average. Altogether, the uniformity of mean stress from point to point may be considered to be much better than exists in most track. It is evident that the uniformity is influenced by such things as uniformity of rail bearing from tie to tie by reason of lesser variations in play between rail and tie bed, uniformity of bearing of rail on tie-plate and tie, and lack of great variation in stiffness of tie support.

It may further be noted that the average of the mean stresses in base of rail for points opposite a rail-joint is almost the same as the average value of the mean stress at places away from a rail-joint.

In the 52 places measured at location 1, 2, 3, and 4, the stress at the outer edge or inner edge of base of rail differs from the mean of the two stresses by an average of 7 per cent of the mean stress. Of the 52 values, four give an edge stress of more than 20 per cent greater or less than the mean stress, with ratios of 1.31, 1.25, 1.26, and 1.21. Generally the greater stress is in the outer edge, and there are few reversals from point to point. The variations of the edge stress from mean stress may be said to be very small, much less than is to be found in track generally. It should be noted that the lateral bending observed in these tests is principally that due to the condition of the track and not that due to the condition or motion of the rolling stock. The lack of lateral bending stresses may properly be attributed mostly to the uniform bearing of rail on tie-plate and tie-plate on tie and to insuring that the adzed surfaces at the two ends of the tie lie in the same plane obtained by reason of methods used in adzing and boring for the tie-plates and tie. The fact that the ratio of stresses at outer edge to mean stress in base of rail is greater than unity and thus that there is generally an outward bending of the rail may be attributed in large part to the cant of the rail being only 1 in 40;

Fig. 80.—VERTICAL BENDING MOMENT IN NORTH RAIL AND SOUTH RAIL AT THE REAR WHEEL WHEN THE LOAD IS MOVED FROM POINT TO POINT—LOCATIONS 1, 2, 3 AND 4—TESTS ON MISSOURI PACIFIC RAILROAD.

Fig. 81.—LATERAL BENDING MOMENT IN NORTH RAIL AND SOUTH RAIL AT THE REAR WHEEL WHEN THE LOAD IS MOVED FROM POINT TO POINT—TESTS ON MISSOURI PACIFIC RAILROAD.

rails with small cant or no cant have been found most often to give outward bending of the rail and those with large cant to give inward bending.

The values of the vertical bending moments in the rail from point to point, calculated from the mean stress in base of rail, are also given in Table 28. Here, as in the case of stresses, the average bending moment for locations 1, 2, and 3 (155,000 in.-lb.) is less than the analytical moment (185,000 in.-lb.) and that for location 4 (181,000 in.-lb.) is less than the analytical moment (208,000 in.-lb.), although if the points having very small stresses had been omitted in calculating the averages the difference would be smaller. It seems probable that if measurements had been made between all ties the two values would have been more nearly comparable.

In Fig. 80 the magnitudes of the vertical bending moments are plotted to scale in the order of the place in track for the four locations. Except for the points developing relatively low moments the variations along the track may be called small variations from the average.

The magnitude of the lateral bending moment in the rail, calculated from the excess or deficiency of stress at the outer or inner edge of base of rail as compared with the mean stress, is plotted for the east rail and the west rail in Fig. 81 for the four test locations, inward or outward bending from the track being indicated. The scale is similar to that of Fig. 73. Here again it should be kept in mind that the lateral section modulus of a rail is less than one fifth of the vertical section modulus (.194 for the 110-lb. R.E. rail), and hence that for a given lateral bending stress the corresponding bending moment is relatively smaller than the vertical bending moment. The largest lateral bending moments are 10,000 and 7000 in.-lb.—the others are smaller than 6000 in.-lb. and all average 2600 in.-lb. It is evident that the lateral bending in this track due to static load is extremely small, owing, as has been said, to the excellence and uniformity of the bearing of rail on tie-plate and tie-plate on tie. With reference to the direction of the lateral bending, it may be noted that for both rails the bending was in nearly all cases outwardly of the track and only at one inward bending was there a value greater than 2000 in.-lb.

## VII. DISCUSSION OF TESTS OF RAIL-JOINTS

47. **The Function and the Action of the Rail-Joint.**—In the Fifth Progress Report, the action of the rail-joint as a whole and that of the individual joint bars were described and discussed on the basis of the experimental data and its interpretation in the light of analytical considerations. In Chapter VI of that report and in the Review at the end of the chapter, the function of the rail-joint and its principal modes of action were treated quite fully. The additional experimental data and information from track and laboratory tests given in this Sixth Progress Report have confirmed the principal findings of the last report and have given new facts and principles applicable to a fuller comprehension of the modes of action of the rail-joint. In considering the information it will be found necessary to repeat some of the statements made in the preceding report. Besides, in a subject on which so little analytical and experimental discussion is available some repetition may be desirable, especially as repetitions of statements and ideas and views will doubtless aid in getting a better comprehension of the way a rail-joint acts.

In moment-taking properties an ideal rail-joint and the supporting substructure should furnish the same stiffness of track as does the continuous rail at points away from the rail-joint. This condition is not fully attainable. An approach to it may be obtained by combining a rail-joint that is somewhat less stiff than the

rail with a somewhat greater stiffness of the rail support at the rail-joint than elsewhere in such a way that the rail depression will differ only slightly as the wheel rolls along and the evenness and regularity of the rail surface under load will not change much along the track upon the application of traffic. At any rate an optimum of stiffness of rail-joint and a somewhat fuller or stiffer tie support of the rail at and near the rail-joint may be expected to be favorable to the rail-joint. The term moment-taking properties of course does not provide for adequacy of resistance of the rail head to flow, because of the discontinuity at the rail ends, nor does it consider opportunity for longitudinal movement at rail ends with changes in temperature—these and other features must have separate consideration.

In a discussion of the rail-joint the following principles and remarks may be useful in connection with the consideration of the action of joint bars of different forms and the way in which they function:

(1) The joint bars of the usual forms of rail-joints act largely or principally as simple beams with the load they carry applied by the rail head on the upper fishing surface of the joint bars close to the ends of the two rails and with their points of support (reactions) distributed at different places along the base of rail when positive moment (downward bending) is applied (see Fig. 1).

(2) For positive moment the resultants of the bearing pressures of the rail head on the upper fishing surface of the joint bar may be considered to be applied in the neighborhood of the rail ends (the resultant of the pressure being close to the rail end) and on each half of a joint bar two resultants of the bearing pressure of the lower fishing surface of the joint bar on the base of rail (upper surface of flange) will be located, one at 4 in. from the rail end or somewhat more or less and the other farther along toward the end of the joint bar, the positions depending upon bearing fit and other conditions. For worn bars the top resultant will be further from the rail end and the longitudinal distance from this resultant to the interior reaction will generally be smaller than for well fitting bars.

(3) Because of the difference in the flexural curves of the rail and the joint bar under vertical bending moment there is little vertical restraint to modify the conditions of simple beam action, but the lateral restraint given to the joint bar at various positions along its length influences its lateral action and modifies the position of the neutral axis developed at the various sections along the joint bar.

(4) Stiffness of the rail-joint as a whole (resistance to deflection as compared with that of the full rail) is an essential property of a good rail-joint. Besides the need of excellence of fit and absence of play between joint bar and rail, the size and shape of the bar section should be such as to give it the maximum obtainable deflection-resisting properties (stiffness of beam action).

(5) In addition to forcing the joint bar into a place close against the fishing surfaces of the rail and producing lateral restraint in the joint bar and preventing the joint bar from working out of place under bending and twisting action, bolt tension has been found to develop elastic springing action in the joint bar which may be a principal source of the maintenance of bolt tension in rail-joints subjected as they are to repeated movements and wear in track. The value of this springing action and the useful limitations in the magnitude of the bolt tension will be dependent upon the shape and design of the joint bar and the opportunities for useful lateral springing deflection.

(6) The moment developed in a rail-joint in track for given wheel loads is dependent upon the amount and distribution of the tie reactions against the rail developed at and near the rail-joint, as well as upon stiffness of rail-joint and the amount of play and quality of fit between rail-joint and rail. It is evident that relative spacing of ties at and away from the rail-joint and also the relative vigor or effectiveness of tamping joint ties and likewise the differences in the play between rail and rail support from tie to tie all influence the magnitude of the bending moment developed in a rail-joint. The moment developed in the joint bars is almost always less than that in the full rail.

(7) The design of the form of the joint bar (section, longitudinal form, and other properties) is worthy of still further study.

In the articles in this chapter, discussion is given on some of these points, questions are raised in other directions, and comparisons of tests are given.

48. **The Action of Several Forms of Joint Bars.**—A comparison of the mode of action of several forms of bars in rail-joints and of the differences in magnitude and distribution of stresses over their mid-section and of other characteristics, as determined generally in laboratory tests described in Chapter II "Laboratory Tests of Rail-Joints", will be useful in understanding something of the similarities and differences in their action upon the application of load.

The new and unused N.Y.C. and Penn. angle bars for heavy rail (38 and 38½ in. bars for 127-lb. and 130-lb. rail, respectively), described in Articles 7a and 7b, showed excellent fit in the rail-joint throughout. In both joints, the compressive stress at the top of the bar developed at mid-section under load (see Fig. 6 and 8) was double the tensile stress at the gage line near the bottom of the bar, even though the distance from the upper and the lower gage lines to the horizontal geometrical axis was nearly the same. This difference in stress is due to the dissymmetry of the bar section. Longitudinally of the bars the stress at the top decreases rapidly away from the mid-section, while at the bottom it remains nearly constant throughout the middle 8 in. of length of the bar and for a greater distance when the bolt tension is low. These differences may be explained by the changes in lateral restraint of the bar from point to point along the length and their effect in modifying the inclination of the neutral axis of the unsymmetrical section. The angle of inclination of the neutral axis from horizontal at mid-section of the N.Y.C. angle bar was +15° with 20,000 lb. bolt tension and +20° with 2000 lb. bolt tension; at sections 4 in. on either side of mid-section the corresponding angles of inclination were -15° and 0. With the Penn. angle bars the inclination at mid-section was +25° and +25° and at sections 4 in. on either side -45° and 0 for the bolt tensions of 20,000 and 2000 lb., respectively. In both N.Y.C. and Penn. rail-joints, the longitudinal distribution of compressive stresses and bending moments show a peaked form in the middle 8 in. which is less marked at a bolt tension of 2000 lb. than at 20,000 lb. On the application of load the bar at mid-length twisted somewhat, moving slightly outward at the top and inward to a greater degree at the bottom, resulting in a noticeable decrease in the tension of the inner bolts—due mainly to lack of symmetry in the section. The lower bolt tension gave more twisting and bottom lateral movement than the higher tension. The distribution of the stresses over the section from top to bottom at mid-length was similar to that found in bars of similar section given in the Fifth Progress Report.

The rail-joint herein termed the Santa Fe Symmetrical Type Rail-Joint for 130-lb. rail has joint bars closely resembling in section the near-symmetrical study

section F designed for discussion in the Fifth Progress Report (see Fig. 120 of that report). Except for having a length of 26 in. and 4 bolts instead of 39 in. and 6 bolts the joint bars were the same as those in the track tested on the Chesapeake and Ohio Railway. The tests showed that the fit between the rail and the bars of the joint tested in the laboratory was not entirely good, especially in one of the halves of their length. With these near-symmetrical bars and the rail-joint under a uniform moment of 400,000 in.-lb. the stresses and moments developed at the mid-section (see Fig. 13) were found to be the same for bolt tensions of 20,000 and 2000 lb., regardless of possible differences in restraint given by the two bolt tensions in the two tests. It was also found that for both bolt tensions the stresses at top and bottom gage lines had approximately the same magnitude at corresponding points along the length of the bars. This lack of difference in stress at the top and the bottom is attributable to the symmetry of the section and is in marked contrast to the variability found in rail-joints of the angle bar type as shown in the N.Y.C. and Penn. angle bars just discussed. Besides, the stresses, except at areas affected by strong concentration of bearing pressures, correspond closely to the stresses calculated from the applied moment by the ordinary formula of mechanics based on a horizontal neutral axis. A similar correspondence in stresses was observed in the tests of joints of symmetrical section on the Chesapeake and Ohio Railway. It is evident that this form of section acts effectively throughout in the manner of the beam action generally assumed in treatises on resistance of materials except as certain points in the section may be affected by the bearing pressures applied by the rail, all of which is in contrast with the deficiency in stress developed in the flanges of the angle bar form of section.

The lack of good fit in the bars of the joint tested in the laboratory was the source of vertical movement between bar and rail, which contributed to the deflection of the joint. For a bolt tension of 20,000 lb., upon applying load there was a very slight lateral movement outward at the top of the bar at mid-length and a slight inward movement at the bottom (see Fig. 14). At other places, the top of the bar was stationary or moved slightly outward; at the bottom the movement was slightly inward along the whole length. For a bolt tension of 2000 lb. both top and bottom of the bar remained close to the initial position throughout the middle 12 in. At the ends there was outward movement at both top and bottom. The higher bolt tension was accompanied by a somewhat smaller vertical movement between rail head and bar, averaging less than .002 in. closure at the rail ends on application of load and about .002 in. opening at the bar ends for the higher bolt tension, while for the low bolt tension the corresponding values averaged .007 in. closure at rail ends and .008 in. opening at bar ends. The higher bolt tension thus will reduce the amount of movement between rail and joint—the decrease depending upon the fit of the joint.

The pair of the Penn. symmetrical type joint bars for 130-lb. rail (length 38½ in.), taken from a joint in the track at Claymont, Delaware, tested in the laboratory showed results similar to the Santa Fe joint bars (see Fig. 12). The stresses at the top and the bottom of the bars are nearly proportional to the distance from the horizontal gravity axis and agree fairly closely with the calculated stress. The stresses with bolt tensions of 20,000 and 4000 lb. are strikingly similar. The distribution of stresses and moments along the length of the bar are almost identical for the two bolt tensions. The conditions of fit and restraint of the bars are not particularly affected by change in bolt tension. The design of this bar is stocky, with a very thick web. Its section modulus is only 70 per cent of that of the Penn. L-3 angle

bar, and necessarily the stress developed is higher, though not correspondingly so. The results of the tests, however, bring out some of the advantages in the symmetrical form. Only a few bars of this design have been used by the Pennsylvania Railroad.

The striking feature of the tests of the Continuous rail-joint was that in both head-bearing and head-free bars the reflexed flange under the rail did not act entirely integrally with the rest of the section and thus the greater part of this flange was not effective in resisting bending moment in the way that is assumed ordinarily in the mechanics of beam action, and therefore that the maximum stresses are greater than would be expected. At the bottom face of the reflexed flange (see Fig. 16) the stress at the outer edge averaged 20,000 lb. per sq. in. and at the inner edge 10,000 lb. per sq. in. for the head-bearing bars, 22,000 and 10,000 lb. per sq. in. at the corresponding points for the head-free bars, as compared with the analytical value of 19,000 lb. per sq. in. for both points. The stress at the inner edge of the reflexed flange is thus nearly 50 per cent less than the analytical stress at this gage line for the two forms of Continuous joint bars. The center deflections on three longitudinal lines or elements of the length of the head-free Continuous bars located at the top of the bar, at the outer edge of the bottom of the reflexed flange, and at the inner edge of the reflexed flange differed from one another considerably. On the stress diagram at mid-section, no single axis at any inclination could be found for which the observed stresses were proportional to the distances between gage point and axis. The stresses at the top were greater than the analytical stresses based on a horizontal axis. The observed stress at the top of the bar at mid-section for the high and low bolt tensions in the head-bearing bars is about 28 to 40 per cent greater than the analytical stress of 21,000 lb. per sq. in. based on a horizontal axis and in the head-free bars about 10 to 25 per cent higher, though in the latter case it is apparent that because of the position of the rail bearing pressure on the bar the gage line used at the top of the bar does not give the actual maximum stress, which is probably nearer the fillet of the rail. Regardless of this, the maximum stress is less than has been found with other forms of bars, owing of course to the heavy section. The distribution of the stresses at the top of the bars along their length is similar to that of the bars heretofore discussed, except that the stress diagram for the head-free bars is less peaked (more blunted) at the middle of the length than for the head-bearing bars, due both to an outward movement of the top of the bar at mid-length and to the distribution of the bearing load a greater distance back from the rail end—both of which result from the bearing being at the rail fillet. In both forms of bar, the stress at top gage line 4 in. from mid-section is 40 or 50 per cent of that at mid-section.

As just stated, the observed stress at a top gage line at mid-section was less in the head-free Continuous bar than in the head-bearing bar. As the upper bearing of the rail is at the fillet it seems probable that the gage line used on the head-free bar does not give the maximum stress, which may be closer to the bearing area. The bluntness of the stress distribution diagram at and near mid-section is an indication that the load bearing or contact area extends well back from the rail end and that its centroid is farther from the rail end than is usual with the head-bearing bar. The greater slope of a bearing area on the fillet of the rail permits such a variation; the rounding form of the bearing contact may also facilitate a better fit at the two rail ends and possibly also may obviate to some extent the "digging in" of the rail ends at the end to the load bearing contact areas. Upon application of load the vertical movement of the head-free bar with respect to rail at mid-length

is greater than with the head-bearing bar, and the magnitude of this movement is greater as the bolt tension becomes less. This movement and the rather marked increase in tension in the inner bolts upon application of load indicates the desirability of maintaining fairly high bolt tension in the head-free Continuous joint. Even in the head-bearing Continuous joint, high bolt tension is important.

The form of the Continuous bar gives opportunity for adding metal below the rail base and likewise the depth of the bar can be increased and a heavy section obtained. As the reflexed flange does not act fully with the rest of the section in resisting flexure, some ineffectiveness of the added metal must be accepted. However, the form permits the design of a heavy and strong joint bar. With both the head-bearing and the head-free Continuous bar it is essential that the fit between bar and rail be excellent.

In the Muller rail-joint tested, a bearing contact was provided for positive moment on the top of the joint bar for a length of 3 or 4 in. each way from the rail ends and a bearing contact on the base of the rails for about 3 in. from the ends of the bar, and the bearings are limited to these locations. A characteristic of the rail-joint tested is that in assembling the joint a considerable tension must be put into the end bolts to bring the ends of the bars to a bearing on the base of the rail at the ends of the bars for supporting the reactions in acting as a beam, and the lateral bending moment thereby put into the bars develops high initial bending stresses in fibers of the bars at and near mid-section. For the rail-joint tested the initial stresses due to the lateral bending thus developed were found to be 30,000 lb. per sq. in. at the top gage line and 75,000 lb. per sq. in. at the bottom gage line (extreme outside edge of the bottom flange of the bar) on the assumption that the elastic limit of the metal is not exceeded. In the test with a load of 25,000 lb. (vertical moment of 300,000 in.-lb., 75 per cent of that applied to the other rail-joints tested), the stresses at the top gage line due to the applied load were 30,000 and 40,000 lb. per sq. in. compression in the two bars, respectively, and the stresses at the bottom gage line 2,000 and 10,000 lb. per sq. in. tension. It is apparent that the resulting stresses caused by tightening the bolts in setting up the joint and in applying the load of 25,000 lb. averaged 2000 lb. per sq. in. compression at the top gage line and 80,000 lb. per sq. in. at the bottom gage line. Thus the initial stresses put into the bar by tightening the bolts greatly changed the actual stresses present under an applied load. The magnitude of the initial stresses depend, of course, upon the longitudinal form of the joint bar. It is evident that under ordinary track conditions the rail-joint tested would not have opportunity to resist negative moment, for the middle of the span rose .15 in. before developing negative resistance. It may be said then that this rail-joint developed very high initial stresses and that the resulting stresses under load were extremely high, that the large deflections indicate that it is lacking in desirable stiffness, and that it is ineffective in resistance to negative moment.

**49. The Position and Magnitude of the Bearing Loads and Reaction Forces Acting upon the Joint Bars.**—In a number of tests of rail-joints both in laboratory and in track the moments at the various sections along the length of the joint bars were calculated from the observed stresses and plotted to give moment distribution diagrams. For these diagrams bearing loads and reaction forces representing the resultants of the actual forces and similar to those denoted by  $Q$  and  $R'$  and  $R''$  in Fig. 1, were computed which would produce a distribution of moment along the length of the bar approximating that of the real moment distribution curve. Generally four reaction

forces along the length of the bar were assumed in the attempt to fit the moment curve—sometimes only two or three were needed. It should be understood that the position and magnitude of these forces are only approximately correct. Other similar sets of forces might be chosen; the position of a force may be taken an inch or possibly more away from that given, resulting in some changes in the magnitude of the forces required to produce the moments found at the various sections along the bar. The calculated values of the bearing loads and reaction forces at the top and bottom flishing surfaces of the bar found by the method used furnish information that will be helpful in judging of the position and magnitude of the loads and reactions acting upon the joint bars with the wheel over the middle of the joint.

Fig. 82 gives calculated bearing loads and reactions for the laboratory tests for which distribution of moments was obtained. The magnitude reported is the value for two bars of a joint. From the shape of the original moment distribution diagrams (peaked at the middle), it is considered that the two bearing loads (resultants) are applied on the top of the bar quite close to the rail ends, except that in Penn. L-3 (lat. def.) the resultants were found to be 2 in. back from the rail ends and in I.C. joint one resultant was 2 in. back from its rail end. The magnitude of the bearing load applied by the two companion rails generally differed, though it may be seen that in three cases the resultants found are equal. The values of the bearing loads applied by each rail in developing the moment of 400,000 in.-lb. at mid-section of two bars (the moment applied to the I.C. joint was only 240,000 in.-lb.) range from 30,000 to 80,000 lb. on the two bars, which of course are not equally divided between the two bars. Generally there are two reactions acting on each half of the bars, the main one at about 4 in. from the rail end and a second one well out toward the end of the bar. In one joint (Penn. L-3 angle bar No. 1 (lat. def.)), by the deforming process the bottom flange instead of being relieved of contact bearing throughout the quarter region has taken a form that gives a third reaction contact, and in the deforming of the top flange the load bearing contact has been moved away from the end of the rail. For the 38-in. bars the magnitude of the interior reaction generally ranged from 13,000 to 62,000 lb. for two bars and the end reaction from 9,000 to 18,000 lb. For the Santa Fe 26-in. bars the interior reactions range from 9,000 to 39,000 lb. and the end reactions from 26,000 to 34,000 lb. For the I.C. 24-in. bars the distribution is unlike the other joints—the fit is irregular. All the values given are the sum of the pressures on two bars—the division between them in all probability is uneven and likewise the position of the resultants is not the same on the two bars.

Several significant conclusions are brought out from such tests. The position of the bearing load applied by the rail to the bar when the load is at the middle of the joint is necessarily very close to the end of the rail in well fitting bars of the ordinary forms. The form of the flexure curve of the rail for a few inches back of its end and the form of the flexure curve of the joint bar throughout the same location are such that an interior reaction bearing contact is produced along an area not far away from the rail end with its centroid approximately 4 in. from the rail end, as shown in these diagrams. The closeness of this reaction force to the load bearing force, in horizontal distance between the two vertical forces, is productive of a large increase in moment developed in the short length of 4 in. or so. This sudden increase in moment is indicated by a peaked form in the moment diagram. As a consequence high values of both the top bearing pressure and the interior reaction are developed—values which are much higher than would be found if the load bearing pressure and the main reaction were further apart. The closeness of the load bearing contact to the end of the rail, together with

Fig. 82.—POSITION AND VALUES OF BEARING LOADS AND REACTIONS THAT WOULD DEVELOP THE MOMENTS OBSERVED AT SECTIONS ALONG THE JOINT BARS IN LABORATORY TESTS.

the lack of curvature in the rail at its end and with the maximum curvature of the bar coming at the same place, results in a greater detrusion at this place, a "digging in" by the rail end as the statement is sometimes made.

Similarly in Fig. 83 are given moment distribution diagrams and corresponding bearing loads and reactions on two bars for the 39-in. Santa Fe symmetrical type bars tested in the track of the Chesapeake and Ohio Railway at Ashland, Kentucky. The observed moments in the bars at mid-section range from 120,000 to 250,000 in.-lb., val-

Fig. 83.—POSITION AND VALUES OF BEARING LOADS AND REACTIONS THAT WOULD DEVELOP THE MOMENTS OBSERVED AT SECTIONS ALONG THE JOINT BARS IN TRACK OF THE CHESAPEAKE AND OHIO RAILWAY.

ues which are smaller than the moment of 400,000 in.-lb. that was applied in the laboratory and also more variable because of the variability of the tie reactions in the track. There was also variation in bolt tension and in fit of bars and in their position, which contributed to variations in magnitude and position of the loads and reactions acting on the bars. The moment diagrams indicate that the bearing load was applied to the top of the bar close to the rail end, except that in two cases the resultant for one rail was 2 in. from a rail end. In most cases there were two reactions for each half of a bar.

When there was only one reaction and the bolt tension was observed, the bolts had low tension or were loose. With two reactions in each half length the distance from mid-section of bar to position of an interior reaction ranged from 2 to 6 in. The magnitude of the interior reactions was moderate; it ranged for joints with tight bolts from 12,000 to 23,000 lb. at one rail end for two bars, and with low tension from 8,000 to 12,000 lb. or was absent. The end reactions came at 12 in. away from mid-section for five joints and at 14 and 16 in. for five joints; of the latter two had low bolt tension and two tight bolts. Except in the case of low bolt tension, the end reactions were smaller than the intermediate reaction; the range was from 5,000 to 17,000 lb. for two bars.

It is evident that if bars were formed along their length in such a way that there will be relief from reaction bearing contacts for positive moment at places other than towards the end of the bar (absence of reaction at  $R'$  in diagram (b) of Fig. 1 leaving only  $R''$ , or  $R$  as in diagram (a)), the magnitude of the top bearing force ( $Q$  in Fig. 1) will be decreased.

It was also found in the tests that in joints with bars having close fit all along their length, when the wheel load is directly over a section in the region of the quarter points of the length of the bar the curvature of the rail at that point may cause contact on the bar at a nearby point and the moment developed there may be somewhat greater than it is at the same section when the load is directly over mid-section. (See Fig. 23 and 24.) For bars having relief of contact with rail at quarter points of the length, the moment at a given section will increase gradually to a maximum with load over mid-section.

**50. Bolt Tension, Its Function and Action, and the Elastic Lateral Springing of Joint Bars.**—As given in the Fifth Progress Report the purpose of providing tension in bolts may be stated to be as follows: (1) To draw the bar as far into its place between the two fishing surfaces of the rail as the roughness of surface and differences of dimensions of the two rails and the two bars will permit. (2) To prevent the bar working out of place when the bending and twisting of bars and rail may act to force it out. (3) To make the bar fit more closely to the rail and thus to decrease the vertical movement between bar and rail produced upon application and release of load. (4) To give lateral restraint to the angle bar type of joint bar and thus to reduce as far as practicable the deflection of the neutral axis from horizontal and the corresponding lateral bending of the angle bar or other unsymmetrical type of section and also to reduce the twist that accompanies this form of section when a vertical load is applied to the joint. (5) In the case of lateral bending to act as an important part of the moment resisting procedure of the joint, both in the case of small bolt tension and in the case of bolt tension sufficiently high to bring into play integral action in the joint resistance.

It will be remembered too in connection with purpose No. 1 that after a bar has been put in place and the bolts tightened, repeated application and release of load (especially with the development of both positive and negative moment) will result in decreasing the bolt tension as the bar is worked or drawn into closer relation or more nearly complete contact with the rail fishing surfaces, every car adding continued application and release of load. It is apparent that any working into place closer to the rail will act to decrease the magnitude of the bolt tension except as it may be modified by initial bending and springing of the bars or other device for reducing the tension loss. In newly placed joints, one or more re-tightenings after

the joint bars have been worked in under the action of traffic loads will cause the joint to assume a more nearly stable bolt tension.

The working out of place, referred to in purpose No. 2, is more apparent with the angle bar form of joint bars than with bars of the symmetrical type, though the twisting action found when rail and tie-plate bearings are uneven and irregular may contribute somewhat to decrease in bolt tension in any form of rail-joint. It should be noted that tension in the inner bolts tends to pull the bottom of the bar inward toward the rail at mid-length of the bar when under positive bending moment and that the resulting difference in the curvature of the bar and the rail developed near the rail ends frees contact between the lower fishing surfaces of bar and rail at and near mid-length, and also that a corresponding tightening occurs in the end bolts as the upper fishing surfaces are freed near the bar ends, while opposite effects are developed with negative bending moment. The lateral restraint referred to in purpose No. 4 is particularly important with the angle bar or other unsymmetrical form of joint bar, and high bolt tensions are advantageous in producing lateral restraint and reducing longitudinal stresses and in making the bar act more efficiently. It was stated in the Fifth Progress Report that the bolt tension needed for purpose No. 5 in the case of straight track and light curves is within the limits of the bolt tension desired for other purposes.

As referred to in the last paragraph, momentary decrease in bolt tension is found when the top fishing surface of the bar near the middle of the length remains in place against the under side of the head of rail and the lower fishing surface is freed from contact, as occurs when a positive moment is applied, especially with the angle bar form. Similar conditions are found at the ends of the bar. Twisting movement of the rail-joint may give similar changes in tension. These changes are largely elastic, but repeated applications of load will give conditions that tend toward permanent reductions in tension.

Wear of bar and rail at fishing surfaces is productive of loss in bolt tension, particularly in the inner bolts. Tightening the inner bolts, however, does not usually bring back the full contact at the top bearing near the rail ends, for except with untreated bars little wear is to be expected above these bolts, and with wear at the top fishing surface near the ends of the rail play between rail ends and bar will remain and hence greater deflection of the joint as a whole—an undesirable condition. With bars having requisite excellence of fit, made of suitably thermally treated steel, and having properly maintained bolt tension, together with adequate and uniform rail support, the wear should not be a troublesome factor.

As stated in the Fifth Progress Report, four bolts in a rail-joint may be said to be sufficient. In the angle bar the end bolt is of most service when positive moment is applied and the inner bolt for negative moment, and in the symmetrical bar both bolts will be useful for both conditions, and in both forms the inner bolt and the end bolt are effective in developing resistance to lateral bending. However, it is evident that advantages accrue with the use of six bolts. A loose end bolt or a loose intermediate bolt or a loose inner bolt will have its function taken at least partly by an adjoining bolt. Either the end bolt or the intermediate or inner bolt will give desirable restraint for resisting vertical bending moment, and all bolts that have a fair amount of tension will be useful in resisting lateral bending in the joint. The number of bolts need not be fixed by the length of the joint bars or by the question of supported versus suspended joints, for six bolts have been used very satis-

factorily with bars 27 in. long (commonly thought of as a short bar) in suspended joints and would apply to a supported joint. The cost of the two additional bolts and of their maintenance will need consideration in weighing the advantages.

Article 10 "The Lateral Springing of the Joint Bars Due to the Application of Bolt Tension and Vertical Loads" gives pertinent information on the part played by the bending of the joint bars for 130-lb. rail in maintaining bolt tension when "working in" or wear tends to decrease the tension. In this connection it will be well to bear in mind that the elastic stretch in a 1-in. bolt of the length ordinarily used in rail-joints is only about .005 in. for a bolt tension of 20,000 lb. Extremely slight movements of the two bars toward each other would, of course, cause a loss in this stretch and therefore a loss in the tension, since with the ordinary pitch and no distortion of the bolt thread and nut thread a movement of .005 in. would correspond to only one twenty-fifth of a turn of the nut. However, the spring of the bar by its bending under application of bolt tension is such that a movement of the two bars considerably greater than .005 in. will not cause full loss in tension or any large part of it. For the data reported in Article 10 the movement of a nut in tightening from 5000 lb. to 20,000 lb. is 10 to 20 times the corresponding stretch of the bolt (or more). In unwrenching, the same change in tension was accompanied by a much smaller movement of the nut, so that the effectiveness of the flexure of the bar is less than that in wrenching, but the tests show that flexure in the bar is an important factor in maintaining bolt tension. As in the case of many spring washers, the travel of the spring through the lower range of tension is large and that in the higher range is smaller. Since the important part of the range may be said to be between, say, 5000 and 20,000 lb., the characteristics through that range should be noted in judging of the effectiveness of the bars in maintaining bolt tension. It is evident from the data and from the smallness of the stretch of a bolt that tensions beyond 20,000 lb. are relatively ineffective in holding joint bars in place, since a relatively small movement of the bar causes a loss of considerable tension. It follows that the wrenching of bolts to a tension of 40,000 or 50,000 lb., as is sometimes practiced, gives little useful result in maintaining bolt tension, and it may be productive of ill effects in other ways such as excessive resistance to temperature movements.

The desirable magnitude of the bolt tension then may be said to be limited, in one way, by the limit in effectiveness of the lateral flexural action of the bars in maintaining tension under changes in lateral position of the bars by wear or otherwise, or by the effective range given by any auxiliary device used for the same purpose. For the joint bars tested this upper limit may be called 20,000 lb. A lower limit may be set by the least magnitude which will hold the bars in proper position to function properly. A further advantage in the higher tensions lies in reducing the play and deflection of the joint; this will be considered in the next article. It is evident from analysis and tests that the unsymmetrical bar needs a higher bolt tension than the symmetrical bar. The dissymmetry of the ordinary angle bar form is helped in efficiency and in reduction in deflection by the higher bolt tensions, and with the higher bolt tension there is less swinging inward of the bottom of the bar at mid-length. The principal disadvantage of a very low bolt tension for the symmetrical type of bar is the resulting greater deflection in the whole rail-joint and probably a greater wear.

The tests herein reported confirm the finding given in the Fifth Progress Report that for the symmetrical type of bar a minimum bolt tension of 5000 lb. may be expected to give satisfactory conditions for both vertical bending and lateral bending on straight track and light curves. The corresponding minimum tension desirable for the angle bar may be given as 10,000 lb. The upper limit of useful tension for the ordinary forms of rail-joint may be thought of as 20,000 lb. These values apply to track conditions after the bars have been worked into place and approach a fairly stable position. It should not be forgotten, of course, that the higher bolt tensions increase the resistance to movement of the rail in the joint with changes in temperature, but the movement will take place in the joint and in the rail end that has the least resistance to movement, and under usual conditions only a part of the joints will move, whether the bolt tension is low or high. The movement is so difficult to control that there is probably no advantage in this respect in maintaining a low bolt tension within the limits of tension given above.

In this connection it may be noted again that for all purposes of the rail-joint the standard 1-in. high-strength bolts are of ample strength, even with 130-lb. rail. The greatest strain on the joint bolts results from eccentricity of bearing of head and nut against the bars due to obliquity of surfaces. With accurately finished extensometer bolts the increase in stress along one side of the bolt due to bending was considerable (see Table 15). With ordinary bolts and nuts the additional stress given by eccentricity of bearing and the resulting bending of the bolt will be the source of a considerable part of the maximum stress developed in the bolt.

**51. Fit and Play in Rail-Joint, Vertical Deflection of Joint Bars and of Rail-Joint under Load.**—In the tests in both laboratory and track, as in those reported in the Fifth Progress Report, it was found that the fit between the rail and joint bars varied considerably, and that with poor fit the vertical movement between rail and bar on application of load and also the deflection of the rail-joint as a whole was much greater than with well fitting bars. With increased vertical movement between rail and bar and the greater deflection of joint and the consequently greater inelastic downward movement at the rail ends when loaded comes a lessened magnitude of the moment developed in the rail-joint in the track (see Fig. 82, 84, and 88 of the Fifth Progress Report) and in the rail adjacent to it. It follows that there is also a greater depression of the joint ties under load and usually, too, a consequent lowness of the rail support. All of these detract from ideal conditions in the rail-joint and contribute to the defects found in track.

For what may be classed as well fitting joints the vertical movement between rail and joint bars at either the rail end or the bar end upon application of load averaged in the tests about .001 in., with a maximum vertical movement, .002 to .003 in. (see Fifth Progress Report, p. 286). The rail-joints with poor fit but tight bolts gave vertical movements as high as .01 in. With low bolt tension the vertical movement was much greater. Tightening the bolts generally reduced the vertical movement though not always. Vertical movement and play facilitate wear at the bearing points on fishing surfaces; conversely, with lack of vertical movement between rail and bar on application of load the wear is minimized and with hardened bars it is relatively small, and the conditions of deflection, depression of rail support, opportunities for resisting bending moment, and other functions of a rail-joint are enhanced. It may be repeated that a fit that gives the smallest vertical movement practicable between rail and bar at the critical areas of contact is a most important element of a satisfactory rail-joint.

The deflection of a well fitting rail-joint in a span of 48 in. tested in the laboratory with a load at mid-span ranged from 1.5 to 1.8 times that of the full rail when the bolts were tight. For low tension (2000 lb.) the ratio was 2.0 or more. With poorly fitting bars the ratio is considerably greater for both high tension and low tension. The bars used in the laboratory tests, even those called poor fit, had much less play than many that may be found in track. Play due to either original poor fit or wear is a source of increased deflection. The value of the moment of inertia of the section and the inclination of the neutral axis with respect to a horizontal line also affect the deflection of the joint. The test of the Muller rail-joint showed a deflection 3.6 times that of the full rail. The laboratory tests bring out the need of requiring a high standard of fit of bars as well as having excellence of design.

In the tests of track of the Chesapeake and Ohio Railway, for the rail directly opposite a joint the lines connecting the deflections in 66 in. for light and heavy loads (see Fig. 55) are approximately parallel to each other so that the deflection of the full rail may be called proportional to increase in moment in rail between the light and the heavy load. The deflection for the light load, however, is smaller or greater than this proportion, owing doubtless to variations in play and stiffness of support at and near a point opposite joint for which the deflection was taken. So far as the deflection of the rail-joint and rail is concerned, the trend of the deflections as shown by the line in Fig. 55 is roughly proportional to the moment developed at mid-section of joint bars, and even the lines which may be drawn connecting the points for medium and light loads would be found generally to be roughly parallel to the average line. The deflections of the rail-joints in 66 in. may be said, then, to be fairly proportional to the increase in moment developed in the joint regardless of how play and stiffness of the rail support may be varied. It was found, too, that the average deflection of the rail-joint in 66 in. is roughly  $1\frac{1}{2}$  times the deflection of the full rail for the same moment.

**52. The Rail-Joint under an Advancing Load and Effect of Speed on Stresses and Bolt Tension.**—The laboratory tests on rail-joints under advancing load made by advancing both load and supports by increments of 6 in. toward and beyond the middle of the joint approximated in some ways the conditions of the joint in track. The distance from load to either support (24 in.) was shorter than the distance from wheel load to point of zero moment in the rail in track, which is ordinarily from 30 to 45 in. and includes two or more tie reactions at one side of the wheel load. The tests gave no evidence of any sudden changes in the deflections, movements, or stresses within the rail-joint that would produce undesirable accelerations or impacts as the load passes over the rail-joint. The bars of the rail-joints tested fitted the rails well enough to give a gradual development of stresses and vertical movements.

With the excellently fitting 38-in. N.Y.C. bar for 127-lb. rail used in the principal advancing load tests made, no moment was developed at mid-section of the bar when the forward support reached the rail ends, as is to be expected. At this loading, however, moment was developed at sections between mid-section of bar and the approach end (see moment distribution diagram for load at *B* Fig. 24). This is doubtless because with the excellence of fit the bar in this portion bends with the rail. With the load at 12 in. left of the rail ends and the forward support at 12 in. right of the rail ends the moment in the bar under the load is about half of that at mid-section. The distribution of the moment along the bar will be de-

pendent upon the fit between the bar and rail from point to point along the bar and the differences in the flexural curves of bar and rail. However this distribution may vary; a bar that fits the rail well along the length will give the peaked effect shown in Fig. 24 for the load at  $F$  (mid-section) and the accompanying high concentration of bearing pressure near the rail end.

The advancing load tests made with the shorter bars (Santa Fe 26-in. symmetrical bars and I.C. 24-in. angle bars, see Article 8), although not so complete as the tests made with N.Y.C. 38-in. bars, gave results which are in most ways similar to those obtained with the longer bars. The moments at eleven sections along the length of the Santa Fe bar for the various positions of the load are given in Fig. 26. The poorer fit between rail and right half of bar (see Fig. 14 for vertical movement between bar and rail) has produced some irregularities in the corresponding part of the moment diagrams. As would be expected, the extra moment developed in the first quarter and last quarter of the length of the bar because of the compelling curvature of the rail above the bar through this portion, as the wheel rolls along, is considerably less than in the 38-in. bar. As the bars used in the I.C. joint were somewhat worn and the fit for one of the halves of the bars was poor, differences in stresses were shown in the two halves. With a bolt tension of 20,000 lb. the extra magnitude of the moments in the first part and last part of the length was noticeable, but the hump was not present with a bolt tension of 2000 lb. and there must have been enough leeway so that the curvature of the rail did not act to bend the bar throughout these portions. With the low bolt tension the movement between bar and rail was increased considerably.

It should be noted again that with the long bar and to a slight extent with the short bar and with good fit a secondary load bearing may be developed on the top of the bar near the quarter point of the length as the wheel rolls over this region, evidently due to the downward curvature of the rail at this point being greater than that of the bar when the wheel is over or near this spot (see Article 8 "Action of a Rail-Joint under an Advancing Load").

In the tests on the Pennsylvania Railroad with the electric locomotive running at various speeds up to 90 miles per hour, the form of the record of the stress in the angle bar at mid-section and at 8 in. from mid-section corresponds to the form of the influence lines made up from the advancing load tests of the laboratory except as the several tie supports and the negative moment developed in the track modify the conditions. At the higher speeds the records were not always entirely definite and free from the effects of vibration.

The observed stresses in the joint bars in the tests on the Pennsylvania Railroad give important information upon the effect of speed of the locomotive on the stresses and moments developed in the rail-joints. The stresses and the moments at mid-section calculated from the observed stresses are given in detail in Tables 8, 9, 10, and 11. Since the condition of rail support differs considerably at the various joint locations, it has seemed well in making comparisons on the effect of speed to express the moment in terms of the average analytical moment in the full rail under static loading for points away from a joint—a value which is termed the joint moment ratio. The moment in the full rail at a speed of 5 miles per hour may be expected to be approximately the same as that developed in the rail if static load tests had been made with the given wheel loading. The values of the joint moment ratio for the several speeds used are recorded in Table 29. The values given (ex-

cept as otherwise noted) are the average of three or more runs and represent the average of the moments developed in the two bars of a rail-joint at mid-section under two drivers of electric locomotive 7850, which had a nominal driver wheel load of 37,500 lb. In further explanation, it may be stated that a joint moment ratio of .50 means that the moment developed at mid-section of the two bars of a rail-joint is .50 of the average moment developed in the rail itself at points along the track away from the rail-joint under static application of the same wheel loading,

TABLE 29

Effect of Speed on Joint Moment Ratio—Tests on the Pennsylvania  
Railroad at Claymont, Delaware

The Joint Moment Ratio is representative of the moment developed in the joint bars relatively to the average value developed in the rail at 5 miles per hour. Except as otherwise noted the values are the averages of three or more runs at the given speed.

| Test | Joint Location and Bars | Speed in Miles per Hour |     |      |       | Remarks                       |
|------|-------------------------|-------------------------|-----|------|-------|-------------------------------|
|      |                         | 5                       | 45  | 70   | 90    |                               |

\*One run only.

†Two runs.

which may be taken to be approximately the same as the same wheel loading will give at a speed of 5 miles per hour. It will be seen that the increase with speed for any of the tests is not large. In some tests there is a decrease, as in test (i). Naturally some irregularity is shown in the speed effect in some of the tests.

It should be noted that these tests were made on different joints, with differences in bolt tension, and with bars changed from one joint location to another and even with bars shortened from 38½ in. to 24 in., and of course with diverse conditions of tie support. Details of the condition of the various rail-joints are given in Chapter III "Tests of Rail-Joints on the Pennsylvania Railroad" but a brief statement of the conditions may be helpful here. In Table 29 the first number in the column headed "Joint Location and Bar" gives the location of the joint in the track (see

Fig. 33) and the second number gives the number of the joint at which the bars were originally located; thus, "4-5" in test (d) means that the test was made at joint location 4 with bars that were originally at joint location 5. The joint in test (a) (38½-in. angle bars) had been undisturbed for two months under heavy traffic and had an average bolt tension of 29,000 lb. In test (b) (the same joint) the average bolt tension had been decreased to about 2000 lb. and a .005 in. thickness gage could be inserted along the length of bar for 3 and 8 in. at the two ends of the bars and 2 to 6 in. at their middle. In test (c) the same bars had been sawed to a length of 24 in. and re-installed with a bolt tension of 28,000 lb. Tests (d) and (e) were made at the same joint location (4) with 38½-in. bars taken from joint location 5 and bolt tensions of 14,000 and 12,000 lb. The joint in test (f) (joint location 5, the same bars as in tests (d) and (e)) had remained undisturbed under heavy traffic for several months and the bolt tension was 14,000 lb. The bars of test (g) were laterally deformed and had been installed in joint location 1 only a few days and had a bolt tension of 12,000 lb. In tests (h) and (i) the bars from test (g) had been installed a short time at joint location 3 and were tested with bolt tensions of 23,000 lb. and 13,000 lb., respectively. Test (j) was made on track No. 1 on a joint with 38½-in. bars and an average bolt tension of 2000 lb.—a track with large traffic not in as good condition as track No. 4 where most of the tests were made. The joint location of test (k) was on track No. 4 away from the other test locations and the joint had not been disturbed for a long time. The bars were 24-in. angle bars and the bolt tension averaged 6000 lb. Test (l) (joint location 3) had symmetrical bars which apparently fitted poorly at the base. The symmetrical bars in test (m) (joint location 2) combined the detrimental effects of poor fit at the base and low bolt tension.

In making comparisons of the values of the joint moment ratios found at the various speeds for the several rail-joints used and for their different conditions, it is best to look for trends rather than specific ratios of increase with change of speed. Test (a) gives only a slight increase in moment and stress in the joint from 5 to 90 miles an hour. Test (b) on the same joint with very low bolt tension gives a much larger increase, but one of the three runs at 5 miles per hour gave a low value and the average ratio for the other two was .44, and one of the two runs at 90 miles per hour gave a moment at the second driver double that found on the other run thus indicating a considerable transfer of load to the opposite second driver on one run. The trend in test (b), however, is a considerably greater increase than in test (a). Test (c) gives over 20 per cent increase from 5 to 70 miles per hour. Test (d) with another set of bars at the same location gives a similar rate of increase. Tests (g), (h) and (i) with a pair of bars placed at two joint locations gives only a small increase to 70 miles per hour. The value 1.18 in test (g) in the one run at 90 miles per hour is 36 per cent greater than that found at 5 miles per hour. Tests (j) and (k) made on joints in two tracks which had not been disturbed for a long time gave little change from 5 to 70 miles per hour, as did joints 3-3 and 2-2 in tests (l) and (m).

Altogether the effect of speed on the stresses and moments in the joint bars was not large. For most of the tests with tight bolts the changes were not more than may be expected from variations in transfer of load from one wheel to others, independently of an increase from speed. Two of the tests showed an increase of 20 per cent from 5 to 70 miles per hour. The few runs at 90 miles per hour gave

a higher rate of increase, test (b) (low bolt tension) showing more than 50 per cent, test (g) 36 per cent, but test (a) less than 10 per cent. Although the effect of speed of the locomotive on the stresses developed in the rail in the tests at Claymont have not yet been reported, it may be said that the effect is not greater for the joints than may be expected for the rail in the same track if track is at least in good condition. Only a single run at 90 miles per hour in test (g) gave a moment in the joint bars greater than the average value to be expected in the full rail at points away from a joint for static loading or at a speed of 5 miles per hour.

It should be noted, of course, that the dynamic augment involved in the counterbalancing of steam locomotives and some forms of electric locomotives provides an additional source of increase of stress in rail and joint bars with increase in speed which was not present in these tests. With the electric locomotive used, a source of the variation in values of the stresses and moments at a given joint lies in the variation in wheel load applied at the joint in individual runs by transfer to the other wheel on the same axle or to a lesser extent to other wheels on the same rail. The transfer of wheel pressure to the companion wheel occurs when a greater lateral pressure is exerted against one rail than against the other, as when a locomotive oscillates laterally about a vertical axis. The oscillations were much more apparent at 90 miles per hour than at 70 miles per hour, and the variations are noticeable in the tests.

It will be seen from Table 29 that the conditions of rail support at a given joint location exercise a strong influence on the magnitude of the moment that may be developed in a joint if the different bars are well fitting. The values of the joint moment ratios and likewise of the corresponding moments developed, as well as the general increases with speed, for tests (a), (c), (d) and (e) are quite comparable, although the placing of a different pair of bars at the joint location in tests (d) and (e) results in somewhat larger values, which are somewhat the same as those found with these bars in their original location (test (i)). Tests (g), (h) and (i) at two other joint locations develop higher values. Tests (j) and (k) on track which had not been disturbed for some time and were found to have low bolt tension gave considerably smaller values.

It is well to remark that the tests were made on joints having bars that were not worn—even those that had been in track for some time under heavy traffic showed small wear and little play. The tie and ballast substructure was substantial and in good condition. The conditions, then, did not favor the development of impact in the joints nor the formation of high stresses in the bars, as may be expected in track in poor condition.

The changes in magnitude of the bolt tension (increase or decrease) at the time a driver passed over the joint were relatively small at the speeds of 5, 45, and 70 miles per hour on the three joints tested. See Article 22 "Changes in Bolt Tension Under Moving Loads" for details of tests and findings. The increases or decreases in the tension in the bolts in the joints tested (joints 4-5, 3-1, and 9-9) while under the load for the three speeds ranged from zero to 2000 lb., and in a few cases to 3000 lb., even with low tension in the bolts, values which are comparable to those found in static tests in the laboratory. The sign of the change in tension, whether positive or negative, was generally similar to those found in static tests in the laboratory. The change in tension here considered is distinct from the loss of tension

upon the repetition of passage of wheels after bars have been newly placed in track. The conclusion from the tests is that the magnitude of the changes in bolt tension during the passage of a train is not of great importance. It is to be expected that an even smaller change in magnitude will be found with symmetrical bars, since they do not have the same degree of tendency to swing inward at the middle and outward at the ends as have the angle bars.

**53. Miscellaneous Remarks on the Rail-Joint.**—In Chapter VI "General Discussion" of the Fifth Progress Report\*, a discussion is given in some detail concerning the action of the rail-joint in track, the flexure within the rail-joint, the influence of the shape of sections, and other matters bearing on the design of the joint bar. Further consideration will now be given to the rail-joint.

### 1. Shape of the Section.

The analysis and tests given in the Fifth Progress Report permit comparisons to be made of symmetrical and unsymmetrical sections of bars. The angle bar form of section was originally adopted because a greater moment of inertia with respect to a horizontal geometrical axis for the limited fishing height may be obtained. Generally, however, the area below the horizontal axis is larger and less effectively placed than the area at the top. It was shown in the Fifth Progress Report that the angle bar section under vertical bending moment deflects downward and inwardly, with a neutral axis inclined to the horizontal, and consequently that the stresses resisting a given moment may be considerably greater than found by the ordinary assumptions of beam calculation. When there is little or no lateral restraint the inclination of the neutral axis of the angle bar at its middle is 45° or more and for some shapes part of the flange may be in compression instead of tension in resisting vertical bending moment. A well fitting angle bar held by tight bolts receives considerable lateral restraint, which modifies the flexural action of the bar, decreases the angle of inclination of the neutral axis, and thus limits the increase of stress above that obtaining with the neutral axis horizontal. In the region of mid-section, where the moment to be resisted is the greatest, values of the inclination of the neutral axis in well fitting angle bars with tight bolts in track were found to be as much as 25° to 35° giving an excess of stress of 20 to 35 per cent over those calculated with a horizontal neutral axis, while in joints under less favorable conditions the value reached 45° and the excess of stress 60 per cent. Worn bars and low bolt tension are conducive to the development of higher stresses for a given bending moment, but it should be noted also that in the track these conditions generally resulted in the development of a low moment in the joint, thus reducing its effectiveness in performing the functions of a joint. It is well to note, too, that these conditions markedly increase the deflection of the joint as a whole. Evidently excellence of fit and proper bolt tension are especially essential to securing satisfactory service in the angle bar form of rail-joint.

When the bar section is symmetrical with respect to the horizontal geometric axis, the application of a vertical bending moment results in a vertical deflection and the stresses are proportional to the vertical distance from this axis, even without lateral restraint, except for any twist that may be given from the bearing loads and reactions of the bar not being in the same plane. Symmetry of section is thus advantageous in promoting efficiency in flexural resistance, in avoiding lateral deflection from vertical loads, and in obviating the need for more than moderate bolt tension. With the limited fishing

---

\* Proceedings, A.R.E.A., Vol. 31 (1930), p. 273.

height available and the limitations imposed by the presence of the wheel flanges it may not be feasible to design a truly symmetrical section that will have enough metal in the flanges to keep the resulting fiber stress down to a desired limit and meet the requirements of an economical section. Because of this and because the effect of slight dissymmetry is modified by a small amount of lateral restraint, it may be found advantageous to vary somewhat from true symmetry.

A study of the analysis and stresses of near-symmetrical joint bars given in Article 55 "The Design of Joint Bars" of the Fifth Progress Report leads to the conclusion that a dissymmetry that requires the application of a lateral restraining moment equal to one

tenth of the applied vertical moment ( $\frac{M_y}{M_x} = 0.1$ ) to maintain the neutral axis in a

horizontal position may not be considered objectionable. A fair fit and moderate bolt tension will give this amount of lateral restraint to the bar, and even with looseness the additional stress developed under free bending is found to be less than 10 per cent. The relative value of the lateral restraint needed to maintain the neutral axis in a horizontal position may be obtained from the geometrical properties of the section by making  $\tan \alpha$  equal to 0 in equation (47) of the Fifth Progress Report (equivalent to maintaining

the neutral axis in a horizontal position), which then becomes  $\frac{M_y}{M_x} = \frac{J_{xy}}{I_x}$ , where  $I_x$  is

the moment of inertia of the section with reference to the horizontal gravity axis and  $J_{xy}$  is the product of inertia with reference to the horizontal and vertical gravity axes.

If the value of  $\frac{M_y}{M_x}$  given by this equation is not more than 0.1, the dissymmetry will

not be serious. The C. B. & Q. proposed section for 110-lb. rail and study section F for 130-lb. rail (see Table 31 and 32, Fifth Progress Report) are within the suggested limits of dissymmetry and to give a horizontal neutral axis require a lateral restraint equivalent to a lateral bending moment in the region of mid-section amounting to .08 times the vertical bending moment developed at the same section; with a restraint less than this amount the stresses are increased less than the 10 per cent named above. The Santa Fe near-symmetrical section for 130-lb. rail used in laboratory tests and in tests on the track of the Chesapeake and Ohio Railway, which has a section similar to study section F of the Fifth Progress Report, requires an even smaller restraint. The limit of 10 per cent for the lateral restraint needed to give a horizontal neutral axis results in small variations from the action of the symmetrical bar. Sections within this range of dissymmetry may be included in the term "symmetrical type of bar".\*

In the matter of the deflection of the bar and the rail-joint in track, for bars of the symmetrical type the full value of the moment of inertia of the section with reference to the horizontal gravity axis may be used in determining vertical deflections and making comparisons of the stiffness of joint bars without serious error, while for the usual angle bar a value of two-thirds of the moment of inertia of the section or less has been found applicable throughout the middle part of the length of the bar. The stiffness of the symmetrical bar as compared with the angle bar is thus considerably greater than is indicated by a direct comparison of the moments of inertia.

\* It should be noted that while exact symmetry is not essential any dissymmetry should be such as to make the lateral component of an oblique deflection caused by a vertical bending moment to be directed inwardly of the joint rather than outwardly. It may be said further that as the lateral restraint of the bar in the rail-joint referred to is not under control some obliquity of deflection of the joint bar may occur (even with exact symmetry, due to conditions of fit between bar and rail) and that therefore some variation from vertical movement must be expected. However, a dissymmetry less than the limit of 10 per cent will have advantages.

The Continuous joint bar by means of its reflexed flange gives an opportunity to place additional metal well away from the horizontal geometrical axis of the section and thus to develop a greater strength in the bar, but it should be understood that the reflexed flange is not fully effective in giving the resistance to flexure that is ordinarily assumed for sections acting integrally and the stiffness of the bars in the joint will not be proportional to the moment of inertia of the section. The reflexed flange involves the use of a different tie-plate at the joint and a lowering of the level of the joint ties.

Regardless of the general type of joint bar and considering the limitations of the fishing height, a well designed section requires that the top flange or head be large enough to balance the lower flange as far as is practicable and also that the areas of the two flanges be so placed as to minimize dissymmetry of section with respect to the horizontal axis such as that found in the angle bar and the Z-bar section. In the design of the flanges of the joint bar, the size of the bolt heads and nuts and their position may make limitations.

## 2. Fit and Longitudinal Form.

In the discussions of the rail-joint emphasis has been placed on the importance of close fit between bar and rail in reducing play and wear and increasing markedly the effectiveness of the joint in moment and deflection resistance and thus decreasing the amount and cost of maintenance. The tests have shown that load bearings and reaction bearings between rail and bar on application of wheel loads are developed at certain points along the length of the bar for both positive moment and negative moment. For positive moment the load bearing forces usually are found at and near the rail ends and the resultant reaction forces at two points on the base of rail in each half of the length of the bars (see Fig. 1, 82 and 83). It seems well to consider the position and relative magnitude of these forces and to consider whether it is possible and proper to further control their position and magnitude. In the present discussion new or unworn bars are considered.

In Fig. 84 suggested positions of controlled bearing contacts along the top and bottom of the bar are shown for three lengths of joint bars; it should be borne in mind that the amount of the relief desired is greatly exaggerated in the figure. It is evident that for positive moment it is desirable to have close fit at the best place along the load bearing area at the top of the bar. It is also evident that it would be well not to have load bearing contact right at the rail end nor for a short distance back of it—this to prevent concentration of pressure on the bar close to the rail end where the bar is curved but the rail is straight and makes an angle with the direction of the curve of the bar while under load, and also to avoid the cutting action of a sharp edge at the extreme end of the rail. This means that freedom from load bearing contact for a short distance back of the rail end (say, a half inch) would be advantageous. Such a gap between the bearing areas of the two rails, too, would leave some opportunity for local adjustment. Next to this gap at the middle of the bar each way a length of  $2\frac{1}{2}$  inches or so for the top load bearing contacts would seem to be sufficient. Away from these areas of contact a freedom from contact for some distance along top of the bar until a controlled end bearing is reached would appear to be advantageous for the reason that the designed bearing near the rail end would continue to be maintained even after some wear occurs or even when there are slight variations in fit. The relief from contact in the intermediate region would permit lateral springing action to be developed in the bar by the bolt tension to maintain the bars in proper position with respect to the rail.

With reference to the reaction bearing contacts on the lower fishing surface, it should be pointed out first that with a bar that fits all along its length the lesser curvature of

the rail toward its end under positive moment results in the base of the rail at its end being directed away from the bottom of the bar and thus there will be a freeing of bearing contact at the lower fishing surface close to the end of the rail. The moment distribution diagrams for such bars show that an interior reaction bearing contact (see Fig. 82 and 83) exists a short distance back from the rail end, its resultant or centroid being generally about 4 in. back from the rail end, or somewhat more. This closeness to the position of the top load bearing pressure (4 in. or so longitudinally between the resultants of the bearing pressure and the reaction) is necessarily accompanied by a large magnitude in the top bearing pressure, sometimes excessively large, and this condition may also be a contributor to the wearing back along the top fishing surface of the bar.

Fig. 84.—POSITION OF CONTACTS AND RELIEFS FOR CONTROLLED BEARINGS.

If a length of base contact of say only 2 in. each way from mid-section were provided for the bearing contact resistance to negative moment, a relief of the base contact for some distance beyond would obviate the development of any reaction force in this region and in this way a considerable reduction in the magnitude of the load bearing pressure at the top fishing surface would be made. The base bearing contact for positive moment would then be provided along the remainder of the length of the bar.

For resisting the negative moment, bearing contact along the top of the bar well away from the middle part of the length, perhaps corresponding to the end reaction bearing suggested for the bottom of the bar, should be provided, which together with the provision for bottom bearing close to mid-section will give fishing contacts for forces

that resist negative moment (see the loads and reactions shown by dotted lines in Fig. 84).

The control of the load bearing contacts and reaction bearing contacts at definite places along the length of the bar may be expected to locate the bearing forces between bar and rail at advantageous positions for both positive and negative moment. Such an arrangement will avoid the difficulties and secure the gains referred to in the last three paragraphs. The resulting fit between the bar and the two rails at the contact areas will be improved over that otherwise available with the ordinary variations in bars. Some minor variations in fishing height at the two rail ends may be overcome by the bending and twisting of the bars in tightening the bolts. When wear or other change occurs, the tightening of the bolts may bring back contacts at the same places so that proper bearing conditions will be renewed. As mentioned previously, tension in a bolt placed at the middle of the non-fishing part of the bar will develop a spring having some travel which will be useful in holding the bar in place against wear and lateral movement. On the other hand, the greater length of bar taking flexure with the controlled bearings will result in some increase in the deflection of the rail-joint, unless counteracted by the better fit obtainable.

The desired limitations of reaction and load bearing contacts can be effected by forming or deforming the bar vertically or laterally or both. Care should be taken that the relief from bottom bearing contact should continue closely enough to mid-section to ensure freedom from the development of a reaction force near mid-section, as is seen generally to exist in Fig. 82 and 83 and in other tests that have been made, and yet leave a sufficient length of contact to make adequate provision for base bearing contact in resistance to negative moment. The lateral stiffness of the lower flange of the angle bar makes this precaution more important.

Whatever means are used in shaping the bar to restrict the bearing contacts to specific locations, the control must be such as to ensure relief from reaction and load bearing contacts except at the designated places. The transition to and from bearing contacts should not be abrupt. The clearance in the relieved portions need not be large, better not more than .05 in.

The form of the Muller rail-joint tested provides reaction bearing contacts only for a few inches at the ends of the bar and thus minimizes the magnitude of the load and reaction forces developed in the bar under the positive moment, an advantageous condition. At the same time, in changing from positive to negative moment a considerable upward movement in a span of 48 in. was made (.15 in.) before negative resisting moment was developed, and under the negative moment the resultants of the load and reaction were so close together horizontally that the magnitude of these bearing forces was relatively very large. Under these conditions, too, the interval between the release of positive moment and the lifting of the rail to where negative moment would begin to be developed is so large that for track having moderate or high stiffness of rail support the construction would fail to possess the usefulness of negative resistance at the rail-joint.

The caution against the high initial stress developed in the Muller joint bar by tightening the end bolts, suggests also the need of caution in regard to more than small vertical or lateral curvature of any bar (vertical or lateral camber, if the term camber may be applied to lateral deviation from straightness of bar). With even what may seem to be a moderate variation from straightness, the stress put into the joint bar by tightening bolts has been found to develop high installation stresses, which when added to the

stress due to loading (especially where the conditions of the rail support are conducive to high negative moment) may develop excessive bending stresses. Even though the curvature may give desirable characteristics, it is something which needs careful control, especially with the stiffer bars, and this control may well be embodied in specifications and inspection.

A somewhat similar condition exists in bars which are worn for some distance away from mid-section. The tightening of the inner bolts bends the middle of the length of the bar laterally and twists its top inwardly and in effect lifts the middle of the bar so that the upward and inward moments developed result in initial tensile stress in part or all of the top flange. If the tie supports at and near the joint are in such position as to produce a relatively high negative moment in the joint bars upon the passage of a train, the combination of the high initial tensile stress in the upper flange and the tensile stress of the negative bending moment will result in the formation of relatively high tensile stresses in the top flange. This combination is a source of the breakage of bars from the top, which is not uncommon.

### 3. Size and Spacing of Joint Bolts.

As already noted, considering the limitations of usefulness in the total tension applied by a bolt, a diameter of 1 in. in a bolt that is properly heat-treated may be called adequate, even taking into account possible high bending stresses due to eccentricity of bearing on head and nut. A larger size, with the accompanying increase in the dimensions of head and nut, is likely to interfere with the placing of desired areas in the flanges of the bars.

It is appreciated that within the range of bolt spacings ordinarily used no large differences in effects will be found. However, certain comments on bolt spacing will be made without giving specific dimensions. The end bolts for either short or long bars and with either four or six bolts may well be placed as close to the ends of the bar as will not result in breakages through the bolt holes; the shorter the distances from the end the less the outward curl of the end when the joint is loaded—the part of the bar more than 2 in. beyond an end bolt adds little to the effectiveness of the bar. The inner bolts may well be placed as close to mid-length of the bar as will not result in breakage of rail or bar through the bolt hole. A close spacing between the two inner bolts will facilitate taking up wear near mid-length, though close fitting along the top fishing surface beyond the inner bolts will interfere with such adjustment. With a bar having controlled bearing contacts and six bolts (see Fig. 84), the intermediate bolt holes may well be half way between the inner edge of the end bearing contact and the edge of the middle bearing contact. This position will make the intermediate bolt closer to the inner bolt than to the end bolt. Illustrative spacings are shown in Fig. 84 for three lengths of bars. For bars without controlled bearing contacts an equal spacing from intermediate to end bolts and to inner bolts would be satisfactory. The remarks apply to both angle bars and symmetrical bars and also to joint bars with straight or continuous fishing surface and to those with controlled bearing areas, though the angle bar with controlled contacts may not develop as much lateral restraint as it will with continuous fishing surface. Slight variations in bolt spacing are not important—a move-ment to uniformity in practice would be advantageous.

The vertical position of the bolt holes may well be chosen low enough to best permit placing a sufficiently heavy head of bar to make a well-balanced design (for a large well-designed head is essential for strength and stiffness) and yet to facilitate nut clear-

ance. The center of the bolt hole need not be at the gravity axis of the rail or the bar. It will be seen that the design of the joint bar and the position of the bolt holes with respect to the web height of the rail are interrelated. The D. L. & W. drilling for 130-lb. R.E. rail, which is at mid-height of web, gives opportunity for maximum area of bar flanges for a bar that is reversible in vertical position and has two sets of fishing surfaces, but a much stiffer and stronger bar is possible if not made reversible. The lower drilling of the C. & O. Railway and A.T. & S.F. Railway ( $2\frac{3}{4}$  in. above base of rail,  $5/16$  in. below mid-height of web) will not permit the design of a reversible bar, but it does give opportunity for a stiffer non-reversible bar than is possible with the D. L. & W. drilling such as is exemplified in study section F. Similarly the lower drilling of the N.Y.C. 127-lb. rail, which is  $7/64$  in. below mid-height, gives abundant space for heavy top and bottom flanges for the bar. The drilling of the newly adopted 131-lb. R.E. rail, which is  $1/32$  in. below mid-height of web, is adapted to a reversible form of bar as well as to a non-reversible form—with a lower drilling study section G hereafter shown could have been made somewhat heavier. In general for any rail section, a drilling that is, say,  $\frac{1}{4}$  in. below the line of mid-height has advantages in that a heavier top flange may be provided.

#### 4. Length of Joint Bar.

The tests confirm the statements made in the Fifth Progress Report that the length of the so-called short bar gives adequate opportunity for development of resisting moment. In either short bar or long bar, if the load and reaction bearing areas are not controlled or restricted, a large part of the moment is developed within 4 to 6 in. of the middle of the length, especially with well-fitting bars and moderate or high bolt tension. A length of 27 in. has been found to give satisfactory spacing for six bolts. A length of 38 or 39 in. upon application of load gives a somewhat smaller vertical movement between rail and bar at the bar end as compared with short bars having the same general qualities of fit, but it has not been found to decrease the vertical movement at the rail end—vertical movement at this point depends largely upon the fit between bar and rail for a given joint. The longer length does not aid in reaching a tie support—it is the rail and not the bar which is supported by the tie-plate and tie. With either length the bars should have a sufficient degree of hardness to give proper resistance to wear. No great advantage in a length of joint bar longer than 27 in. is apparent from the tests. If a longer length were wanted to give greater spring travel in a joint bar with controlled fishing contacts, a length of 32 in. would seem adequate for this purpose. The metal in the additional length to make 38 or 39 in. may well be used in getting a heavier section of bar.

#### 5. Lateral Bending.

In the discussion in the Fifth Progress Report it was concluded that allowance should be made on straight track and light curves for a lateral bending moment equal to 10 per cent of the maximum vertical moment ordinarily developed and that the lateral bending moment will not reach 20 per cent under ordinary conditions of traffic and track, and also that for lateral bending moment greater than 10 per cent there will be a sufficient margin of safety in the resistance of the ordinary rail-joint to prevent failure in the joint in ordinary good track. It was concluded from the tests that a bolt tension of 5,000 lb. or more will bring the joint structure into a degree of integral action sufficient to greatly decrease the lateral bending stresses in the joint bars below those developed when the bars resist bending by individual beam action alone, as is found to be the case with very low bolt tensions. With the bolt tension of 5,000 lb. or more it

was found that for a lateral bending moment equal to 10 per cent of the maximum vertical bending moment the stresses developed in the joint bars, either angle bars or symmetrical bars, will not greatly tax the strength of the bar, especially as the fiber developing the highest vertical bending stress will not ordinarily be the one that develops the highest lateral bending stress, and thus that the maximum stress in combined vertical and lateral bending will be less than the sum of the maximum bending stresses for the two bending actions.

**54. Design and Comparison of Joint Bars.**—In the effort to approach toward some of the conditions of an ideal rail-joint—a stiffness similar to that of the full rail and thus the same depression of rail at the joint as elsewhere, and also adequate strength—it is well to formulate some of the qualifications and characteristics of the joint bar that may be expected to contribute to optimum conditions in the rail-joint in these respects. Certain desirable features may be named—fit, adequate stiffness, sufficient strength, moderate magnitude and intensity of bearing pressure between rail and bar, minimum wear, and satisfactory section and longitudinal shape of bar. Other features, perhaps commonly accepted, need not be discussed here.

### 1. Discussion of Qualifications.

Fit between bar and rail at certain important points along the bar (and with it lack of play) is essential to proper stiffness of joint, to smallness of deflection, and to the minimizing of wear—in fact it ranks high among the qualifications for good joints. The excellence of fit in the joint bars of the Delaware, Lackawanna and Western Railroad in the tests described in the Fifth Progress Report, the small value of the movement between bar and rail on application of load (the sum of the movement at four points of a bar—two ends of the bar and end of two rails—ranging from .002 to .005 in.), and the smallness of the vertical deflections are one of the sources of the excellence of service given by the rail-joints in this track. Excellence of fit may well be considered a most important requirement for joint bars. Specifications and inspection should stress close requirements even at the expense of some increase in cost.

It should be accepted as a principle that the stiffness of the track at the rail-joint (resistance to depression under load) should be as near to that of the full rail as is practicable. Besides excellence of fit, stiffness of the bar itself is important in obtaining this result. The need of gaining more stiffness in the joint bars may be judged from the fact that many forms of bars in effect have a stiffness in two bars less than 20 per cent of that of the full rail and that at best but little more than 40 per cent may be attained.

Many joint bars are low in available strength. In the heavier rails, having relatively greater fishing heights, it is not difficult to design a section that will give adequate strength. For calculations and comparisons the magnitude of bending moment used in the discussion in the Fifth Progress Report, 400,000 in.-lb. in two bars, may be considered as applicable to the common conditions of well-kept track with ordinarily heavy rolling stock, and the corresponding stress of 35,000 lb. per sq. in. as a proper working stress—both applicable whether the weight of rail is medium or heavy. It may be added that the strength of joint bars does not need the same improvement as the fit, the stiffness, and the resistance to wear. Poor fit and wear of bar may result in break-ages which are largely due to causes that increase the stresses beyond those due to bending moment.

The magnitude of the bearing pressures between rail and bar at certain areas along the length of the bars is high. The data of the laboratory tests on unused joint bars

give evidence of a load bearing pressure near the end of one rail amounting to as much as 80,000 lb. on the two bars (40,000 lb. on one bar, see Fig. 82), and a similar pressure applied by the contiguous rail. Although the area of the load bearing contact resisting this pressure is uncertain, the intensity of pressure will be great and the opportunity for abrasion of metal with the accompanying movement of rail on bar will be large. A source of the high load bearing pressure is the closeness of one reaction bearing to the end of the rail—frequently 4 in. away—making the arm of the moment produced by this reaction relatively small. The removal of this reaction to a position a greater distance from the rail end, which may be effected by properly controlling the position of the reaction contact areas, will reduce the magnitude of the bearing pressure. Such control will be useful also for other purposes.

Wear along the upper fishing surface is increased by high magnitudes and concentrations of bearing pressure. Abrasion accompanies the slipping movement of rail over bar back and forth as a wheel rolls over the joint—a movement due to the differences in the amount of shortening of the fibers on the top surface of the bar and of those on the under side of the head of the rail in the flexure of the joint under load, as well as to the movement of rail head along the top of the bar due to the longitudinal thrust of the rolling wheel, especially on the receiving rail. Although the movement is small the abrasive action under high concentrations of pressure will be troublesome with mild metal. Play between bar and rail will also increase the wear. Suitable hardening treatment of the metal of the bar or of the parts in the region of the load bearing area will remedy the trouble. Control of the position of the reaction bearing areas will also be helpful. Usually little wear is found at the reaction contact areas (the contact areas being greater and the strains less) and also at the load and reaction bearing areas for negative moment, where the pressures are smaller and the strains less.

In designing the bar section, it is obvious that the following should have consideration: (a) an economical arrangement of metal over the section to secure the requisite stiffness and strength; (b) an approach to symmetry of section with respect to the horizontal axis; (c) for some conditions also an approach to symmetry with respect to the vertical geometrical axis; and (d) a form of section that will be favorable to manufacture. An allowance of space for wheel flanges and for bolts and nuts may limit the size of the top flange. Requisite stiffness and strength relative to that of the rail will involve a study of the upper limits of sections to fit the available space. Distorted I sections within allowable limits of dissymmetry will generally give the best approach to filling requirements for stiffness and strength, though for some conditions a section that has symmetry both horizontally and vertically is preferable, especially for reversibility in the joint. A form which is favorable to uniformity in the finished bar after passing through the rolling and cooling processes has advantages. For rail sections of about the same area, as, for example, the 130-lb. P.S. rail and the 131-lb. R.E. rail, which have effective fishing heights of about 3.9 and 4.7 in., respectively, the greater fishing height of the higher rail furnishes the opportunity for designing a much stronger and stiffer bar. Likewise, for two sections with similar proportions, the heavy rail will have advantages over the lighter one in the strength and stiffness of the joint bar that may be designed. For the lightest weights of rail some form of angle bar may best fit the limitations of the rail section.

## 2. Comparison of Sections.

Values of certain geometric properties of rail sections and sections of joint bars (including several study sections) are given in Tables 1 and 2. In making comparisons of stiffness and strength of bars as affected by their form of section, recourse may be had to

their moments of inertia and section moduli (or instead of the latter the corresponding stress values for any given bending moment), both on the assumption of a horizontal neutral axis and by making suitable allowance for the effect of dissymmetry of section in the track in the case of angle bars. In Table 30 (besides certain properties of sections, which are in the usual units) are given the ratios of the sectional area of two bars

to that of the rail ( $\frac{A}{A_0}$ ), the ratio of the vertical stiffness of two bars to that of the rail as represented by the ratio of their moments of inertia with respect to a horizontal axis

( $\frac{I}{I_0}$ ), and the ratio of the calculated or analytical extreme fiber stress in two bars to that in the base of rail when resisting a given vertical bending moment on the assumption that the neutral axis of the bars remains horizontal. There are also given estimated values of the stiffness ratio and the stress ratio intended to represent values which are available in well-kept track,  $I'$  being the estimated effective moment of inertia and  $s'$  the corresponding fiber stress likely to be found in track service for a given vertical moment by reason of conditions of dissymmetry of section under the lateral restraint usual in well-kept track. It should be added that the effective moment of inertia used in estimating the relative vertical stiffness and relative stress of the unsymmetrical bars under track conditions is the same as  $K_x$  given in equation (57) of the Fifth Progress Report.

The decrease in stiffness ratios and the increase in stress ratios for the unsymmetrical bars given in Table 30 for track conditions over those based on a horizontal neutral axis were obtained from the data of tests in this report and also in the Fifth Progress Report for the track of several railroads on which tests were made. Discussion on these matters may be found in Chapter VI "General Discussion" of the Fifth Progress Report and particularly in Article 54 "Influence of Shape of Section of Joint Bars upon Resistance to Flexure". The values of the tangent of the angle of inclination of the neutral axis for unsymmetrical sections in these track tests ranged from .3 to 1.0. The val-

ues of the ratios  $\frac{I'}{I_0}$  and  $\frac{s'}{s_0}$  given in the table are the estimated average values to be found in well-kept track; they may be considered as representative of track in general good condition. With low bolt tension and poor fit of bar the values of the ratios would be poorer; on the other hand more favorable conditions may give better values.

The joint bars named in Table 30 are for rail ranging in weight from 90 to 152 lb. per yard. The angle bars referred to in the table except the B. & O. bar have been tested in track. They may be considered to represent the heavier forms of angle bar for the given weights of rail; the B. & O. bar shown in section in Fig. 85 is especially heavy. The C. & N. W. skirtless, the C. B. & Q. proposed I section and the A. T. & S. F. joint bars may be considered to be of the near-symmetrical type. The sections of these three and of study sections C, E and F are given in Fig. 117, 119 and 120 of the Fifth Progress Report. Study section F is quite similar to the section of the Santa Fe symmetrical bar tested on the Chesapeake and Ohio Railway, which is shown in Fig. 3. Study section G\* and Pennsylvania symmetrical bar F-4 for 131-lb. R. E. rail and Pennsylvania symmetrical bar F-1 and study section H for 152-lb. P.S. rail are given in Fig. 86 and 87. Study section I\* for 112-lb. rail is shown in Fig. 85. The section shown by the full line and the values given in Table 30 are based on a rail drilling at middle of the web

\* Since this report was submitted study sections G and I have been modified from the form given in Fig. 85 and 86 by removing a narrow vertical strip from the outside of the outer lower flange. The properties of the revised sections are somewhat different from the values given in Table 30.

TABLE 30

### Ratios of Properties of Sections of Joint Bars to the Corresponding Values for the Rail

$A_0$ ,  $I_0$  and  $s_0$  are the sectional area, moment of inertia and fiber stress for a given bending moment, respectively, for the rail, and  $A$ ,  $I$  and  $s$  the corresponding values for two bars on the assumption of a horizontal neutral axis.  $I'$  and  $s'$  represent values available under track conditions. For the symmetrical type of bar,  $I'$  is considered to be approximately equal to  $I$ .

\*The inclination of the neutral axis of the I. C. bars tested in track in their original condition ranged from about  $15^\circ$  to  $45^\circ$ , with resulting corresponding  $\frac{I'}{I_0}$  of .37 to .18 and  $\frac{s'}{s_0}$  of 2.2 to 2.7. The maximum inclination was found with worn bars and low bolt tension.

height. If the center of the bolt hole were lowered to  $2\frac{7}{8}$  in. above the base, a better balanced upper flange of the bar shown by the dotted lines in Fig. 85 could be designed

having  $I$  for two bars 25.9 and  $\frac{I}{y}$  10.9.

It will be noted from the table that the areas of two bars range from .75 to 1.16 of the area of the full rail. Several of them are close to 1.00.

The ratios of the stiffness of two bars to that of the full rail as indicated by their respective moments of inertia with account taken of the effect of dissymmetry upon the

stiffness for unsymmetrical bars give a means of judging of the stiffness of the joint bar in the joint; thus for conditions in the track the ratio  $\frac{I'}{I_0}$  of .40 means that the two joint bars in the track together have a stiffness equal to .40 of the stiffness of the full rail, the relative deflection under the same bending moment being the reciprocal of this — 2.50

Fig. 85.—SECTIONS OF JOINT BAR FOR 112-LB. R.E. RAIL AND OF ANGLE BAR FOR 130-LB. R.E. RAIL.

times as great. As the tests of angle bars on the track of the several railroads gave an average inclination of the neutral axis of  $25^\circ$  to  $30^\circ$  (the range being from about  $15^\circ$  to  $45^\circ$ ), the resulting  $\frac{I'}{I_0}$  for the angle bar joints averages about two-thirds of the corresponding  $\frac{I}{I_0}$ . The values of  $\frac{I'}{I_0}$  in the table are considered to be representative of the conditions in ordinary good track. With well fitting bars of the symmetrical type the tests indicate that the values of  $\frac{I'}{I_0}$  in track may be taken as equal to  $\frac{I}{I_0}$ .

It will be noted that the N.Y.C. angle bar for 127-lb. rail has ratios of  $\frac{I}{I_0}$  and  $\frac{I'}{I_0}$  of .41 and .28, respectively, and similarly the Pennsylvania L-3 angle bar for 130-lb. P.S. rail, of .45 and .33. The I. C. angle bar for 90-lb. rail has a considerable range in the

ratios for track conditions, .41 for a horizontal axis and .18 to .37 for track conditions, and a value of .31 may be considered applicable under ordinary good track conditions. The N. C. & St. L. angle bar for 110-lb. rail has a ratio of .39 for horizontal axis and .26 for the ordinary good track conditions. The C. & N. W. skirtless bar (a light bar with light flanges) with good fit and tight bolts has nearly as great a stiffness in track as is indicated by calculations with a horizontal neutral axis. The C. B. & Q. proposed I section for 110-lb. rail may be expected to give a stiffer joint than the preceding bar. Study sections C, E and F (symmetrical type) have good stiffness ratios. The D. L. & W. symmetrical bar for 130-lb. R.E. rail has a light section (the newer rollings are somewhat heavier) but it is reported to have given satisfactory service, due partly to the extreme care taken to obtain close fit and to the decreased spacing of the joint ties as well as to the high-grade condition of the track. Section Penn. F-4, a Pennsylvania joint bar for 131-lb. rail is not a heavy section, but it has a good form. Study section G for the same rail is a stiff bar. Study section H for the 152-lb. P.S. rail indicates what may be done with a heavier section than the Pennsylvania bar, the stiffness ratio being .42 notwithstanding the greatly increased rail stiffness. Study section I for the newly adopted 112-lb. R.E. rail also has a high stiffness ratio, .38; the value of the moment of inertia of two bars, 25.3, brings out the advantages of the new rail section in giving more vertical space for the bars—the values for symmetrical bars of the 110-lb. R.E. rail given in Table 30 are 19.2 and 16.6.

In making comparison of the stiffness of joint bars it should also be borne in mind that the track tests have shown that joint bars in track having a marked inclination of the neutral axis, by reason of either dissymmetry of section or poor fit or wear or improper bolt tension, develop small bending moments and are inefficient in exercising the functions of a joint.

The stress ratios for any given moment (a ratio of extreme fiber stress in a bar to stress in base of full rail,  $\frac{s}{s_o}$  for neutral axis horizontal, and  $\frac{s'}{s_o}$  for estimated track conditions) given in Table 30 have a considerable range. For the assumption of a horizontal neutral axis the extreme fiber stress in the bars ranges from 1.63 to 3.38 times that in base of rail and for average track conditions the estimated ratios range from 1.9 to 3.4. For the study sections, the stresses will range from 1.9 to 2.1 times the stress in rail. In this connection it should be noted that the values of the section modulus for all the joint bars given in Table 2 are based on the uppermost fiber except the Santa Fe symmetrical bars and study section H, which refer to the lowermost fiber. A comparison of the stresses developed in the bars used with the several weights of rail will show, of course, very great differences. For a moment of 400,000 in.-lb. in two bars (the value used in the Fifth Progress Report for design purposes), the calculated extreme fiber stress in the joint bars in pounds per square inch for track conditions on the assumption that the elastic limit is not exceeded are as follows: I. C. (90 lb.), 63,000; C. & N. W. (110 lb.), 60,000; C. B. & Q. (110 lb.), 46,000; study section I (112 lb.), 38,000; N.Y.C. (127 lb.), 41,000; study section C (127 lb.), 31,000; D. L. & W. (130 lb.), 53,000; B. & O. (130 lb.), 33,000; study section F (130 lb.), 33,000; Penn. L-3 (130 lb.), 37,000; study section G (131 lb.), 28,000; Penn. F-4 (131 lb.), 42,000; Penn. F-1 (152 lb.), 33,000; and study section H (152 lb.), 22,000.

With reference to the relative stiffness of joint bars, it is well to note that the maximum variations from a horizontal neutral axis in the unsymmetrical bars are confined to a short distance along the middle of the length of the bar (perhaps 6 or 8 in.) but this part of the length carries by far the greatest moment and consequently has by far the greatest curvature, and this curvature has a marked effect on the total deflection of the bar and upon the total deflection of the rail-joint as a whole. Outside of this middle region the bar has relatively little curvature (nearly a straight line) and the slope of the outer parts of its length is dependent almost wholly on the curvature of the middle portion. The values of the ratios in the table based upon the estimated effective moment

Fig. 86.—SECTIONS OF JOINT BARS FOR 131-LB. R.E. RAIL.

of inertia of the bar in track may then be taken to represent fairly well the relative deflections of the joint bars.

It should not be overlooked that the deflection of the joint bars is only one element in the deflection of the rail-joint. Play between bar and rail, although seemingly a small matter, quite commonly influences greatly the deflection of rail-joint and the consequent distribution of reactions among the ties at and near the joint. Proper fit in the joint, and continued fit, should be emphasized as important elements in securing high-grade rail-joints.

55. **Spacing of Joint Ties.**—The conclusion that a decreased spacing at the joint ties below the normal spacing has a great influence toward securing no greater depression at the rail-joint than elsewhere along the rail and in avoiding low joints in well ballasted track should receive favorable consideration. Due to the lesser stiffness of the rail-joint as compared with the full rail and also to any play between rail and joint bars, a greater demand is made on the rail support at the rail-joint than elsewhere when the support is uniformly stiff along the length of the rail. This decreased tie spacing is an effective agency in improving conditions up to the point where the greater stiffness of

Fig. 87.—SECTIONS OF JOINT BARS FOR 152-LB. P.S. RAIL.

the tie support becomes troublesome or objectionable, especially at the full rail opposite the joint. The increased vertical stiffness of the rail support is due both to the greater number of ties per inch of rail and, what is more important, to the greater vertical stiffness of the ballast resistance because of the greater horizontal pressures developed in the ballast between more closely spaced ties for well-tamped track. This increased stiffness of the rail support at the joint ties has two effects (1) an increase in the vertical tie reactions (upward pressures) acting on the rail at and near its ends as compared with what is usually taken per inch of length of rail elsewhere with equally well tamped track, and (2) because of this change a reduction in the magnitude of the positive bend-

ing moment put into the joint bars by reason of the greater concentration of vertical reactions produced in the neighborhood of the rail-joint. With decreased spacing (the tamping remaining the same), then, the bending moment put into the joint bars is lessened and, besides, the deflection at the joint is decreased and the depression of the rail at this point is lessened. It is evident also that notwithstanding that the load on the ties per linear unit of length of track will be greater than elsewhere the added restraint in the ballast makes it capable of carrying the greater load if the depth of ballast is adequate. It is apparent that by proper spacing of joint ties the somewhat lesser stiffness of the rail-joint as compared with the full rail may be overcome and the vertical depression of the joint may be kept comparable to that of the full rail elsewhere. The foregoing statements assume that the rail-joint itself is of good design and fit and in proper condition—otherwise the moment developed in the joint bars may be relatively small and the joint will fail to perform its proper functions.

The extent of the decrease in the tie spacing that will give most satisfactory results can best be learned by experience. Two items need be taken into account in considering the problem of the best spacing—(a) the degree of effectiveness obtainable in tamping the track for the smaller spacings used and (b) on the other hand the possibility that the joint ties may be given so much decrease in spacing that hard supports in track will be produced at or opposite the rail-joints and thus be objectionable.

In Article 56 "Miscellaneous Features of Rail-Joints" of the Fifth Progress Report the effect of decreasing the spacing of ties at and near the joint was discussed at some length. It was concluded that the decrease in tie spacing should be arranged symmetrically with respect to the rail ends, two or four smaller spacings for a supported joint and three or even five smaller spacings for a suspended joint—even though rail creepage may later disturb the symmetry—making the outer spacings somewhat greater than those near the rail ends. The practice of the New York Central Railroad on the track tested was to make the two spacings at the supported joint  $16\frac{1}{2}$  in. instead of the 21 in. average for the other ties, and that of the Delaware, Lackawanna and Western Railroad was to space  $19\frac{1}{2}$  in. between the two ties at the suspended joint and 21 in. elsewhere. It would appear that a decrease in the spacing of the ties at and near the joint of 10 to 15 per cent below that used elsewhere may be expected to give satisfactory results with fairly stiff bars. If light bars are used or the bars are poorly fitting the spacing should be even less.

It should be accepted as a principle that so far as the number of tie spacings to be given a decrease in spacing and the amounts of these decreases are concerned, the length of the bars (whether short or long) and the type of the joint support (whether suspended or supported) will not enter into the problem, for it is the rail that is supported by the tie-plate and tie—the bar does not come in contact with the tie-plate—and for any ordinary form of joint bar the same change in stiffness of support will apply to different types. Features of slot spiking or of tie-plate fastening or other accessory matters may lead to preference for one way or another of arranging the joint ties, but generally even these differences may be arranged independently of whether the bars are short or long or whether the joint is suspended or supported. The notion that the joint is supported just in the length of the bar is not tenable. With such decreased spacing at the joint the track foreman will doubtless find that with substantial ballast of an adequate depth it will be unnecessary to tamp joint ties harder than other ties—a practice that seems to be not uncommon regardless of instructions to the contrary.

## VIII. DISCUSSION OF TESTS OF TRACK

56. **The Analytical Consideration of Depressions, Stresses and Moments in Rail.**—In Chapter II of the First Progress Report "The Action of Track as an Elastic Structure"\* a mathematical analysis was given and formulas developed for the depressions, upward pressures and bending moments in rail in track having a continuous elastic support for a single wheel load. For points away from the wheel load the distance from the wheel is then expressed in terms of  $x_1$  (distance from wheel load to point of zero bending moment in the rail). The master diagram there given and reproduced here as Fig. 88 permits finding graphically the depressions, upward pressures and bending moments in the rail at any distance from the wheel load in terms of the values at the given wheel. To find the effect of a combination of wheel loads upon depression and pressure and bending moment in rail, as may occur with a given locomotive or a group of car wheels, the values found from the equations and diagrams derived for a single wheel load are utilized by means of the principle of superposition; that is, by considering that at any given point along the rail the combined effect of two or more wheel loads is the algebraic sum of the effects of individual wheel loads computed according to the distance from each of the wheels to the given point. The effect that each wheel load produces at any given point can be determined from the master diagram by the method outlined above, and the cumulative effect may then be found by adding algebraically the component magnitudes produced by each wheel load. Illustrations of component magnitudes and their cumulation may be seen in Fig. 89 and 90.

In this analysis of track as an elastic structure it is assumed that the rail is supported continuously on an elastic substructure and that this support has a constant modulus of stiffness; that is, that the depression of the track and the resulting upward pressure on the rail are directly proportional to each other. It is further assumed that the track construction is such that negative pressures may be developed under the same conditions of elasticity as are the positive pressures.

In track the ties do not form a continuous support and the support they give is not uniform in stiffness from tie to tie. Further, a variation in play between rail and rail support from tie to tie, especially in track having a very stiff rail support, will cause variations from point to point along the track. The weight of the rail and the downward pull of the substructure on the rail are not ordinarily effective in giving the full amount of negative pressure involved in the analysis to one side of the wheel loads, even though this pressure is relatively small. On the other hand, the use of a modulus of elasticity of rail support  $u$  determined for the usual conditions of the track with the regular tie spacing and an average stiffness of the track substructure gives values of depressions, pressures and moments at the important points on an average fairly close to the values observed in the tests. The analytical negative pressures are generally fully effective in playing their part in the cumulative effects of the several wheel loads for the whole length of the locomotive driver wheel base or the whole length of the two adjacent trucks of two coupled cars, and beyond the end wheels of a group the variations from the analytical values will not ordinarily cause large variations at points for which comparisons need be made. In this connection it may be well to note, however, that although the amount of negative pressure away from the wheel group is relatively small

---

\* Proceedings, A.R.E.A., Vol. 19 (1918), p. 878. A resumé of the equations of the analysis, together with the master diagram, is included in the Fifth Progress Report, Vol. 31 (1930), p. 89.

its distance from a wheel is relatively large, so that its influence must have been applied in some way or the agreement of observed and calculated values at and between wheels would not be as close as has been found. An element in this action will be that if the rail is lifted from its support its whole weight will be available at once to give negative pressure, which though it may be much less than the analytical negative pressure will have a longer length and a greater moment arm than is implied in the analysis. Another discussion of the action of the weight of rail in producing negative pressure at points away from a wheel or group of wheels is given in Article 37 "Values of Modulus of Elasticity of Rail Support." The variation in play between rail and rail support may result in marked variations in stress in rail from tie to tie, which must be taken into account, but the average of observed stresses for spottings of wheels over a short stretch of track has been found to agree closely with the calculated value.

On the whole then it is evident that the analytical treatment has a useful value in discussing the stresses, moments and depressions of the rail and the pressure on the sub-structure, especially in making comparisons of the effect of differing spacing of groups of wheels and of changes in the stiffness of the rail and rail support. It may also be useful in discussing the effect of these variables on such matters as maintenance and deterioration of track. It is obvious, however, that a knowledge of the limitations of the accuracy of the method will lead to shunning great preciseness in its application and to avoiding generalization from minor details or from data on observations at a single spot when other factors (perhaps unknown ones) may have an important influence. It will be seen that a group of wheels rather than a single wheel should be used in making comparisons of moments, stresses, depressions and pressures for combinations of wheel loads.

For convenience of reference some of the principal equations found by the analysis for a single wheel load given in the First Progress Report are given:

$$p = -uy \dots\dots\dots (6)$$

$$x_1 = \frac{\pi}{4} \sqrt[4]{\frac{4EI}{u}} \dots\dots\dots (7)$$

$$M_o = P \sqrt[4]{\frac{EI}{64u}} = .318Px_1 \dots\dots\dots (8)$$

$$y_o = - \frac{P}{\sqrt[4]{64EIu^3}} = - \frac{\pi}{8} \frac{P}{ux_1} \dots\dots\dots (9)$$

$$p_o = P \sqrt[4]{\frac{u}{64EI}} = -uy_o \dots\dots\dots (10)$$

It should be borne in mind that these equations apply directly to a single wheel load—a combination of loads requires the use of the principle of superposition as noted above.

Fig. 88.—MASTER DIAGRAM FOR (1) MOMENT DEVELOPED IN RAIL AND (2) INTENSITY OF PRESSURE AGAINST THE RAIL AND DEPRESSION OF THE RAIL—SINGLE WHEEL LOAD.

The nomenclature is as follows:

$P$  = the weight of the single wheel load.

$E$  = modulus of elasticity of steel.

$I$  = moment of inertia of the rail section.

$x_1$  = distance from wheel to point of zero bending moment in rail.

$y_0$  = depression of rail at the wheel.

$p$  = upward pressure against rail at any given point per unit of length of rail.

$p_0$  = upward pressure against rail at the wheel per unit of length of rail.

$M_0$  = bending moment in rail at the wheel.

$u$  = modulus of elasticity of rail support.

The fundamental equations for the moments, depressions and pressures developed at any given point along the rail by a single wheel load are given in the First Progress Report. Instead of using these long and complicated expressions, the values at a given point may be obtained from the master diagram (Fig. 88) in terms of the values of the moment  $M_0$ , depression  $y_0$ , or pressure  $p_0$  developed at the given wheel. The distance  $x_1$  from the given wheel to the point of zero moment in the rail produced by that wheel load is first found by equation (7), and the distance  $x$  from the given wheel to the given point is expressed in terms of  $x_1$ . The diagram is then entered with this relative distance  $\frac{x}{x_1}$  as the abscissa and the ratio or relative value of moment, depression or pressure given by the corresponding ordinate is taken off. The value at the wheel calculated for the single wheel load by equation (8), (9) or (10) is then multiplied by this ratio. The method of finding the moment, depression and pressure at any point along the rail due to a group of two or more wheels is illustrated in the following article. It should be noted that the modulus of elasticity of rail support  $u$  is the constant used in equation (6) in expressing for any point along the rail the relation between the upward pressure against the rail per unit of length of rail  $p$  and the depression of rail at the same point  $y$ . Thus, for  $u$  equal to 2,000 lb. per in. per in. and  $y$  equal to .20 in., the upward pressure on the rail  $p$  will be at the rate of 400 lb. per in. of length of rail.

In calculating the values given in this report the units inches and pounds are used.

**57. Relations of Rail Properties, Rail-Support Stiffness and Wheel Spacing to Rail Stress, Moment and Depression and to Tie Load and Other Matters That Influence the Durability and Upkeep of Track.**—The calculation and measurements of stresses and bending moments in rail and of pressures and depressions in the track have been found to give data by which certain characteristics of the action of track of different kinds and conditions may be compared and judged. Stresses in heavy rail may be well within a safe value and yet the greater stiffness and stability of the rail may serve a useful and economical purpose not measured by the needed strength. The magnitudes of the vertical movements of the rail upon the application of load (net depressions) give information of value in considering the qualities of track. In this discussion variations in play and stiffness from tie to tie will be neglected and only the net depression will be taken into account. In considering effects on the values of rail depressions, moments, and other elements, it is well to keep in mind that the magnitude of the moment of inertia of the rail section  $I$  is representative of the stiffness of the rail, and that the magnitude of the modulus of elasticity of rail support  $u$  is representative of the stiffness of the rail support, which includes the substructure of the track or part below the rail.

Fig. 89.—MAGNITUDE AND DISTRIBUTION OF BENDING MOMENTS IN RAIL FOR A MIKADO LOCOMOTIVE.

Fig. 90.—MAGNITUDE AND DISTRIBUTION OF BENDING MOMENTS IN RAIL FOR THE TWO TRUCKS OF TWO COUPLED COAL CARS.

In Table 31 are given values of the distance from a single wheel load to the point of zero moment in rail,  $x_1$ , calculated from equation (7) for various rail sections and various values of the modulus of elasticity of rail support,  $u$ . By the analysis the distance from the single wheel load to the point of zero depression of rail is  $3x_1$ , and the pressure of the support on the rail would also be zero at this point. It will be seen from equation (7) that increasing both  $I$  and  $u$  results in no change in  $x_1$ . From Table 31 it will be noted that  $x_1$  has its greatest value for low values of  $u$  and high values of  $I$  (a combination that is not likely to be found in track) and its least values for low values of

TABLE 31

**Analytical Values of  $x_1$ ,  $y_0$ , and  $M_0$  for Various Rail Sections and Various Moduli of Elasticity of Rail Support  $u$**

$x_1$  is the distance (inches) from a single wheel load to the point of zero bending moment in rail.  $y_0$  is the rail depression (inches) and  $M_0$  the bending moment in rail (thousands of inch pounds) at a single wheel load of 30,000 lb.

$I$  and high values of  $u$  (another unlikely combination). For rails from 90 lb. to 130 lb. and  $u$  from 2000 to 4000,  $x_1$  ranges between 36 and 26 in. The value of  $x_1$  for a given stiffness of rail and rail support is a useful quantity in the calculation of moments and depressions in rail and in finding the effect of other wheels by means of the master diagram.

In Table 31 are also given values of the rail depression at a single wheel load of 30,000 lb. calculated from equation (9). It will be noted the rail depressions vary considerably in passing from a light rail to a heavy rail and also in changing from a small value of  $u$  to a large value—differences which will not be found to hold true for a group

of closely spaced wheels. For a single wheel load other than 30,000 lb., the value of  $y_0$  will be proportional to the ratio of the loads.

The value of the moment in rail at a single wheel load ( $M_0$ ) is readily computed by the expression  $.318Px_1$  of equation (8). Values of this moment for a single wheel load of 30,000 lb. are given in Table 31 for several rail sections and various values of  $u$ . For other single wheel loads the value of  $M_0$  will be proportional to the ratio of the loads.

For a group of wheels having fairly close spacing the effect of the other wheels is to decrease the bending moment in rail at a given wheel. The effect of another wheel may be determined by entering the master diagram for moments with the distance from the given section to any wheel load expressed in terms of  $x_1$  and multiplying  $M_0$  by the proportional factor found. The effect of all the wheels is the algebraic sum of the individual effects. The resulting factor by which  $M_0$  will be multiplied may range approximately from .50 to 1.00. For sections at points between wheels the operation is similar. To illustrate contrasts in the form of the moment distribution diagram for different stiffnesses of rail and rail support and different wheel spacings, the values and the distribution\* of the moments in rail for a Mikado locomotive are plotted in Fig. 89. The light lines represent the values produced by the wheels singly, and the heavy lines the resultant value produced by all the wheels as found by taking the algebraic sum of the values shown by the light line. For simplicity the weights on the driving wheels and the trailer are here taken as equal; for unequal wheel loads the process would be the same. In the figure the moments are also expressed in terms of the moment for a single wheel load ( $M_0 = .318Px_1$ ). It will be seen that the moment at the second and the third driving wheels is .51 to .67 times that for a single wheel load of the same weight and that at the fourth driving wheel .57 to .82, while the moment at the trailer is .64 to 1.01. In Fig. 90 are given the values and distribution of moment in rail produced by the two trucks of two coupled coal cars having a wheel load of 25,000 lb. Other wheel spacings, of course, will produce different magnitudes and distributions.

In Table 32 are given values of the moment in rail for the third and fourth driving wheels and the trailer of a Mikado type locomotive. While the moment at the fourth driving wheel ranges from .47 to .86 times that which would be developed with a single wheel, the moment at the trailer for the spacing used varies from .64 to 1.01 times that for a single wheel. In Table 31 it will be noted that for the single wheel the moment decreases as the stiffness of the rail support increases, the value of the moment with a modulus  $u$  of 6000 averaging about .64 times the moment with  $u$  of 1000 for each of the several rail sections, with changing decreases between the two limits of  $u$ . For the fourth driving wheel, however, the moment at the extremely high stiffness ( $u = 6000$ ) is .86 times that for the very low stiffness ( $u = 1000$ ) in the case of 90-lb. rail, and the cor-

\* To illustrate the method of obtaining values at points away from a wheel, assume that  $x_1 = 30$  in. and that the distance  $x$  from the given wheel to the section of rail under consideration is 68 in. Then  $\frac{x}{30} = 2.27x_1$ , and by the master diagram (Fig. 88) the moment at the section produced by the wheel load under consideration is —.20 times the moment  $M_0$  at the wheel. Likewise the rail depression at the section produced by the given wheel is .13 times the depression  $y_0$  at the wheel. The values produced by the wheels of a group are then found by taking the algebraic sum of the values at the given section produced by the several wheels.

responding ratio for 110-lb. rail is .90, for 130-lb. rail .94, and for 152-lb. rail .98. It is seen that the stiffer the rail section the less the effect of increased stiffness of rail support upon the decrease in moment developed in the rail at the fourth driving wheel. Similar comparisons may be made for the other driving wheels. For the trailer the corresponding ratio of the value of the moment at  $u = 6000$  to that at  $u = 1000$  ranges from .74 for 90-lb. rail to .94 for 152-lb. rail.

From Table 31 it is seen that the moment in rail developed at a single wheel would become greater as the rail section increases, the increase in moment being about one third for all values of  $u$  in going from the 90-lb. rail to 152-lb. rail. For the fourth driving wheel (see Table 32) relatively little difference is found at a given value of  $u$  between the moments developed in the several rails. For the trailer the differences increase from nothing at the low stiffness to a considerable difference at the highest stiffness. The stresses developed by the magnitudes of the moment, of course, are inversely proportional to the section modulus of the rail section.

TABLE 32

**Moment in Rail at the Third and Fourth Driving Wheels and the Trailer of a Mikado Locomotive**

Wheel load 30,000 lb. Wheel spacings as in Fig. 89. Moments are given in thousands of inch pounds.  $M_3$  represents moment at the third driving wheel,  $M_4$  that at the fourth driving wheel, and  $M_T$  that at the trailer.

| 6000 | 158          | 191   | 224   | 160           | 199   | 242   | 166           | 209   | 262   | 172           | 217   | 283   |

Except for very heavy rail on substructure with a low value of  $u$ , the moment at the third driving wheel given in Table 32 is smaller than that at the fourth driving wheel. This difference suggests the need of a proper division of the wheel loads and the allowed dynamic augment of unbalanced parts in the design and operation of motive power.

In Table 33 it is seen that the moment in rail at an end wheel of the group for the two trucks of two coupled coal cars (the end wheels giving the greater moment) for 152-lb. rail is about 1.25 times that for the 90-lb. rail through the whole range of values of  $u$ . For any rail the moment at an end wheel with  $u$  of 6000 is about .70 times that with  $u$  of 1000. The moments at the interior wheels have a smaller range of variation. Those at the coupler have more variation in some parts of the table.

For wheel spacings of locomotive and cars other than those given, the variations in moment and stresses due to changes in rail section and in stiffness of rail support will vary from those in the tables, but this discussion may serve as an illustration of changes that will be found.

The rail depression at a single wheel load ( $y_0$ ) may be found from equation (9). It is proportional to the wheel load and depends upon both  $I$  and  $u$ , and it may be called inversely proportional to  $u$  and  $x_1$ . Values of  $y_0$  are given in Table 31 for single wheel load of 30,000 lb. The depression for a group of wheels may be found by taking the proportional factor (positive or negative) from the master diagram of rail depression for the distance from the given section to each of the wheels of the group (expressed in terms of  $x_1$ ) and multiplying the depression ( $y_0$ ) for each wheel load by the corresponding factor and then summing algebraically the effects of the several wheel loads to obtain the cumulative depression. For illustrative purposes in Fig. 91 are plotted the rail depressions for a Mikado locomotive, and in Fig. 92 the rail depressions for two trucks of two coupled coal cars.

TABLE 33  
Moment in Rail at the Wheels and at the Coupler of Two Trucks of Two Coupled Coal Cars

Wheel load 25,000 lb. Wheel spacing as in Fig. 90. Moments are given in thousands of inch pounds.  $M_E$  indicates moment at an end wheel of the group,  $M_I$  that at an interior wheel and  $M_C$  that at coupler.

The analysis shows that the rail depression for a group of closely spaced wheels varies only slightly with  $I$  of the rail section. In Table 34 are given the rail depressions at the main driving wheel ( $y_3$ ) and the trailer ( $y_T$ ) of a Mikado locomotive for several weights of rail and several stiffnesses of rail support and also half-way between the fourth driving wheel and the trailer ( $y_{4T}$ ). It is seen that the depression at the main driving wheel does not vary far from being inversely proportional to  $u$  regardless of the weight of rail. The values for the other drivers are similarly nearly inversely proportional to  $u$ . The weight on the drivers is evidently supported by about the same length of track, and the average depression of rail along this length does not vary greatly regardless of rail stiff-

Fig. 91.—RAIL DEPRESSION FOR A MIKADO LOCOMOTIVE.

ness, and this average depression is nearly inversely proportional to  $u$ . For the wheels of the two trucks of two coupled coal cars given in Table 35 similar relations for the average depression are found. For a given value of  $u$  the maximum rail depression at a wheel is little affected by the rail section, though it is slightly greater for the lighter rails. For the 90-lb. rail the maximum rail depression at a wheel is 15 or 20 per cent greater for  $u$  of 6000 than that obtained from the value at  $u$  of 1000 by the assumption

Fig. 92.—RAIL DEPRESSION FOR THE TWO TRUCKS OF TWO COUPLED COAL CARS.

that the rail depression is inversely proportional to  $u$ . For the other rails the values do not differ much from inverse proportionality. Somewhat similar conclusions may be drawn concerning other types of heavy locomotives and freight cars.

Since the intensity of rail pressure is proportional to the rail depression and to the modulus  $u$  (equation (10)) and since as has just been shown for the main driver the product of rail depression and modulus  $u$  is nearly constant, it follows that the upward

pressure at the main driver is nearly the same for any rail section and any rail support stiffness included in Table 34. For other driving wheels the relation existing between intensity of pressure and  $I$  and  $u$  does not vary greatly from uniformity. In other words, the pressure of rail on individual ties at or near the main driver (and to nearly the same extent at the other drivers) differs little for these several weights of rail and for the range of values of  $u$ . It will be noted from the values of Table 35 that the maximum tie pressure at a wheel of the two trucks of the two coupled coal cars will not differ much for the different rails and different values of  $u$  except that for the 90-lb. rail

the maximum tie pressure will increase from  $u$  of 1000 to  $u$  of 6000 by a total of 15 or 20 per cent. Although the rail depression at a wheel may be greater or less than at points between wheels, depending upon  $l$  and  $u$  and the wheel spacing, it may be expected that the average tie pressure within a group of closely spaced wheels, whether of a locomotive or coupled cars, will not differ greatly through the range of rail weights and of rail support stiffnesses. Evidently the magnitude of the wheel spacing exerts the greatest influence on the tie pressures within the more usual wheel spacings used in such groups of wheels. For longer wheel spacings the variations will be greater and for spacings more than, say, 7 feet the conclusions given above may not apply and a special study should be made. It should be understood, of course, that this discussion assumes relatively small variability in play between rail and tie; for track having much variability in this respect the variations in tie pressure are quite different, as will be seen in Article 59 "Variability in Track and Its Effect".

Assuming then that the average tie pressure throughout the length of a group of wheels, due to given wheel loads, is approximately independent of the rail section and likewise independent of the stiffness of rail support, attention may be directed to the vertical movement of the rail support when this group of wheels moves along the track. From Table 35, it is seen that the maximum downward movement of the rail at one of the four wheels of the trucks of two coupled cars as the wheel loads are applied is about .25 in. for  $u$  of 1500 and .10 in. for  $u$  of 4000. This means for track having little play between rail and rail support that the rail and the top of tie move downward for the less stiff support say 2.5 times as much as they do for the stiffer support. The downward movement within the ballast under the tie will have a somewhat similar ratio of movements. All of the movements are followed by a corresponding rise when the wheels have moved on.

This up-and-down movement under applied and released tie pressure every time a pair of coupled trucks moves by with approximately the same magnitude of tie pressure whether the movement by .25 in. or .10 in., is a form of repetitive loading which, of course, has its effect on the stability of the substructure and on the duration of continuance of good line and surface. It is evident that the effect of repetition will vary in some way with the magnitude of the vertical movement. Although quantitative relations are not known, it is to be expected that the less stiff track will be put out of form with the passage of much less traffic, especially if the track is variable in condition from from point to point and tie to tie. Such a finding is only a restatement of common knowledge that a substantial track substructure having deep and consolidated ballast on a solid roadbed will carry a much greater amount of traffic without maintenance work than will a less stiff substructure.

The data on rail depression were obtained by the application of load statically. Little information is available on the effect of speed on rail depression, and it would be difficult and time-consuming to obtain definite and adequate data on it. Variations in the transfer of load from wheel to wheel and from rail to rail occur with moving loads, especially at the higher speeds, and, besides, there probably is an increase of the load effect with an increase in speed which may be treated as an increase in the load. For the purpose, this increase in load may be thought of as similar to the increase in stress in rail with increase in speed which has been obtained and is recorded in previous progress reports. For rough track the effects of speed will be even greater on tie pressures than on rail stresses.

#### 58. Method of Determining the Modulus of Elasticity of Rail Support $u$ .

—The following article has been prepared in answer to requests for a definite description

of the method used in making determinations of the value of the modulus of elasticity of the rail support by field tests. It will be understood that the principal purpose of  $u$  is for the use in calculating moments and stresses in rail and rail depressions and the corresponding pressures of the rail on the ties. These calculations would be applied to the effect of wheel load and wheel spacing of groups of wheels and to the effect of the dynamic augment and other loads on the rail and substructure of track. The magnitude of  $u$  is representative of the stiffness of the substructure (the part below the rail), which acts as the rail support.

In considering methods of determination it should be kept in mind that the resistance of the substructure to pressure from the rail varies from tie to tie, and especially that the amount of the play between rail and tie bed in passing from the unloaded position to the fully loaded position varies considerably. The determination then must consider the net vertical movement of the rail—that is, the part of the movement that is resisted by tie pressure. A satisfactory method will take into account the average resistance of the ties and ballast in resisting the vertical movement of the load. The greater the variation in this play, the less accurately the calculated values will fit the observed values. Since track will have general variation in depressions and stresses from place to place it will be necessary to make tests at several locations. The effort should be made to test average or usual conditions of the track, though of course the effect of special conditions of track may well be tested separately.

The variations in play and the consequent uncertainty in the load carried by the ties toward the ends of the positive rail depression make it difficult to determine the magnitude and extent of the upward or negative pressure. Because of this and because the amount and distribution of negative pressure outside the wheel base of a group of wheels is rather indeterminate, and because the weight of the rail itself may act to its full amount at a greater distance from the group of wheels than is implied by the analysis, it is best to disregard the upward movement and the corresponding negative effect in the field test for the determination of  $u$ . For points between closely grouped wheels the effect of the negative pressure assumed in the analysis within the length of the group will be fully taken care of by the cumulative effect of positive and negative pressures contributed by two or more wheels. The effect of the neglect of the negative pressures outside of the group upon the value of  $u$  may be estimated as about 3 per cent in tests with a four-wheel freight truck; it will be still less for the two trucks of two coupled cars and for the driving wheels of a locomotive. The depressions calculated from  $u$  determined in this way agree on an average very closely with the net depressions for the length of the group of wheels observed on the same stretch of track. Similarly the observed stresses in rail and the stresses in rail calculated with the observed value of  $u$  agree closely at the wheels. It should be added that the negative pressure away from the group of wheels is itself an important element in the make-up of the magnitude of the moment at a wheel, but the magnitude and distribution of the weight of the rail away from the group of wheels itself apparently has about the same influence as would the negative pressure assumed in the analysis.

In general, then, the assumption may be made that the weight of the closely spaced group of wheels is carried by the ties that are found to have a positive net depression and that the load carried by a tie is proportional to its net downward depression. Since the assumption of the analysis implies a continuous rail support, the track conditions may be approximated by considering that a tie load is distributed over a total distance equal to one tie spacing. For uniform tie spacing the value of the modulus of elasticity of rail support  $u$  for one rail may then be found by dividing the sum of the wheel loads

on one rail by the product of the average spacing of the ties center to center and the summation of the net downward rail depression at each tie considered.

To eliminate most of the effect of irregularities of play and obtain net rail depressions, both a light load and a heavy load should be used in the tests. The weight of the light load should be sufficient to overcome most of the play so that all ties within a given limit of length (say, between the third ties beyond the end wheels of the group) may be expected to carry load. The heavy wheel load may well be greater than the maximum wheel load ordinarily carried by a car, in order that the range between light load and heavy load will be as great as possible. Although the two trucks of two coupled freight cars would be a desirable form of loading, the use of one truck of a freight car is simpler and has been found satisfactory. For the light load a wheel load of 6000 or 7000 lb. is suitable. For the heavy load a wheel load of 30,000 lb. at one end of the car is desirable, though one of 26,000 lb. may be used if a heavier load is not available. The two cars should have the same wheel spacing and be of the same type and should be in such condition that the division of load among the four wheels of the truck will be equal.

In making a test at a given location the rear wheel of the car (either the light load or the heavy load) is carefully spotted at a given point of the rail.

Fig. 93.—VIEW OF SPECIAL LEVEL ROD.

In making a test levels are taken on the base of rail at each successive tie with an engineer's level for the rail unloaded, loaded with the light load, loaded with the heavy load, and again unloaded. A special level rod (see Fig. 93) 6 in. long graduated on the celluloid face to one-hundredth inch has been found very satisfactory for this use. The pointed end of this level rod is placed in a punch mark in the base of the rail made at every desired point. A spherical level bubble at the top of the level rod permits holding the level rod in a truly vertical position. In taking levels the rod is read directly to the nearest hundredth inch or to the nearest half-hundredth. The engineer's level may be set opposite the middle of the truck and about 10 feet from the rail and, of course, must be set low. As the measurement for each point on the rail is found from the difference between readings for loaded and unloaded rail (without calculating elevations), refinements in adjustment of the instrument though desirable are not essential, but the level bubble of the instrument must be held in exact position when reading the rod at every point for every set of readings. Check readings should be taken on a bench-mark close by—better on a bench to the left and one to the right. To ensure accuracy it is well to keep a second man at the instrument watching the level bubble. As extreme accuracy is necessary, the sets of level readings for unloaded and loaded rail must be taken in a continuous operation—the removal of the test car before the completion of the set of readings will result in uncertain data and probably slightly changed conditions in the rail and the load, which would render the work of doubtful value. Trains passing on a nearby track at moderate speed are not likely to affect the levels that may be taken afterwards.

In addition to the rail depression tests, pull-up and push-down tests are needed over the length of rail for which the rail depression test is made. In the push-down test a bar is placed under the rail head and over a fulcrum block resting on the tie at the gage side of the rail, and downward pressure is exerted by a man at the further end of the bar, the spikes or other fastening having been loosened somewhat if necessary to clear the rail base. The pull-up test is made by inserting the bar through ballast under the end of the tie, using a short block as a fulcrum, and then applying pressure at the further end of the bar. Just enough effort is made to bring the rail and tie-plate and tie into contact and not enough to lift the rail. Using methods similar to those of the rail depression tests, level readings are taken on a tack in the top of each tie close to the tie-plate (1) for the tie in the original condition, (2) with the push-down force applied, and (3) with the pull-up force applied; this whole operation takes about one minute for each tie. The differences in the readings at original condition of tie and at push-down and pull-up positions give the magnitude of the play between tie and ballast bed and between rail and tie, respectively. The sum of the two is the play between rail and tie bed. As the readings are taken at a point on the tie away from the rail, the results do not give the exact movement of the tie with respect to the rail, but the values are sufficiently accurate for the purpose intended.

Fig. 94.—EXAMPLE OF GROSS RAIL DEPRESSION AND NET RAIL DEPRESSION MADE BY TWO WHEELS OF A COAL CAR TRUCK.

The data of the tests may be plotted as in Fig. 94. The gross rail depression at a given tie for a given load is the difference between the rod reading with unloaded rail and loaded rail. In the figure the plotted gross rail depressions for the heavy load have been connected by lines, as are also the gross rail depressions for the light load. The ordinates of the derived play curve (AB, for an example) were calculated on the assumption that the light load (6500 lb., CE) has brought the rail and tie to a firm bearing at each tie and that the further depression (CD) made by the heavy load (DG, 30,000 lb.) is proportional to the added load (FG, 23,500 lb.). The calculated net rail depression for the heavy load (BD) leaves a vertical distance (AB), which is termed the derived play and the line connecting their ordinates the derived play curve. The rail net depression at any tie is represented by the distance from the derived play curve to the curve of gross rail depression.

The sum of the pull-up and push-down measurements for each tie are also plotted in Fig. 94 by + marks. It will be seen that throughout the middle portion of the length some of the plotted points are above the derived play curve and some are below it. If a tie within this length is found to carry no load when the light wheel load is applied, it is obvious that adjoining ties carry more than the share indicated by the net rail depression for that load; it follows then that by the method outlined in the preceding paragraph the resulting net rail depressions give values proportional to the average tie loads.

It is evident that the ties at the two ends of the length of the diagram having pull-up and push-down points below the gross rail depression points for the heavy wheel load do not carry load and the rail depression at these ties should be omitted in the calculation of  $u$ . Generally, in the reduction of data, two or three ties outside the wheel loads were included and their depression measured from the derived play curve, even when the pull-up and push-down point is below the derived play curve. Outside of these three ties the vertical distance was measured from the points of the pull-up and push-down test.

The sum of the rail net depression ordinates at each tie obtained as just described is then found; for the data given in Fig. 94, this sum is .97 in. The load on the rail, 60,000 lb., is then divided by the product of this sum of the net depressions and the average tie spacing, 21.3 in. The quotient is the modulus of elasticity of rail support  $u$ , which in the case used is 2900 pounds per inch per inch. It may be added that a somewhat simpler procedure uses the differences between the rail depression for the light load and for the heavy load ( $CD$ ), with the modifications at the ends obtained from pull-up and push-down data as in the other procedure, and takes the difference between the heavy load and the light for the effective load. For example, the summation of the rail depressions for this procedure is .77 in. and the effective load 47,000 lb.

For further details of the method and its applications reference may be made to Chapter V "Track Depressions and Rail Stresses in Tests on the Chesapeake and Ohio Railway" and Chapter VI "Tests of GEO Track on the Missouri Pacific Railroad". As a word of caution it may be well to repeat the statement that because of variability of track the determination of  $u$  should be made at three or more stretches of the track.

**59. Variability in Track and Its Effects.**—In Article 57 "Uniformity and Variability in Track"\* of the Fifth Progress Report a short discussion was given of variations which had been found in track and the accompanying disadvantages. The tests described in this report give more detailed information on the nature and magnitude of such variations and show rather marked contrasts resulting from differences in conditions on the test stretches of two railroads. Both tracks would be called high grade track, well ballasted, and would be considered to be in well maintained condition. Certain features of the two tracks were different. In one certain conditions promoted uniformity of action in the structure; in the other greater variability was found.

In Chapter V "Track Depression and Rail Stresses in Tests on the Chesapeake and Ohio Railway", the test stretches of track on the Chesapeake and Ohio are described as substantial track—new 130-lb. rail, large tie-plates, good oak ties, deep consolidated ballast, and thoroughly compacted roadbed. Although not specially different from ordinary practice the tie spacing and tie width were not very regular, the tie-plate bearings were uneven and partially out of the plane of the rail base, and the play between rail

\* Proceedings, A.R.E.A., Vol. 31 (1930), p. 325.

and tie-plate and tie varied from tie to tie considerably. The traffic was very heavy, but the track had been tamped four weeks before the tests were made. Altogether the track would usually be considered as in ordinarily good or excellent surface and alignment.

In the tests of stress in the two edges of the base of rail made at every other tie, marked variation in both the edge stresses and the mean stress in base of rail at the four locations used was found (see Fig. 70 and 71). In Fig. 95, the stresses at the two edges and the mean stress in base of rail, all given in terms of the average stress along the track as unity, have been plotted for both rails at two of the four test locations, the

Fig. 95.—EXAMPLES OF RATIOS OF STRESS AT THE TWO EDGES AND THE MEAN STRESS IN BASE OF RAIL TO THE AVERAGE MEAN STRESS ALONG THE TRACK.

ordinates of the points along the light full line representing the stress at the outer edge of the rail and those along the dotted line the stress at the inner edge, with the points along the heavy line representing the mean stress in base of rail. The greater stress is sometimes at one edge and sometimes at the other, quickly changing from one side to the other and ranging from nothing at one edge of the base of rail to double the average stress at the other edge and in one case even to three times the average stress. At one place in the tests a compressive stress was developed at one edge having a value of more than 50 per cent of the average mean tensile stress along the track. At one place the stress at one edge of the base of rail was 3000 lb. per sq. in. and at the other edge 28,800 lb. per sq. in., making a mean stress in base of rail of 15,900 lb. per sq. in. as compared with an average mean stress of 9700 lb. per sq. in. at all the places along the same rail. As lateral forces of considerable magnitude will doubtless be developed from the lateral swinging and side thrust of locomotives and cars at high speeds, it is to be expected that the large stress at one edge of the base of rail would be greatly increased under the loads of traffic.

These differences in stress at the two edges of the base of rail and the changes in position of maximum stress indicate a constantly changing lateral bending, sometimes one way and sometimes the other (frequently resulting in unduly high stress at one edge of the rail), and also a marked twisting in the rail. The amount and direction of the lateral bending of the rail from point to point may be seen from the lateral moments plotted in Fig. 73. It should be noted that the measurements were made by moving the load from point to point along the track and always measuring stress in rail directly under the rear wheel, and the movement of the load was such that the pressure of the wheel on the rail was essentially alike in all cases and the wheels were at relatively the same place on the top of the rail, thus applying almost identical vertical and lateral loads at every spot. In considering these variations in stress, it is not a question of the ability of the rail to take these twisting and lateral bending stresses that is of the greatest importance but rather the fact that the tests show extreme variability in the action of the track and a very marked change in the position and direction of the forces applied to the rail by the supports at the ties along the track. The question arises as to what are the causes of the variability and what are the effects on the track (the ties and tie-plates and ballast bed as well as the rail) and on the matter of maintenance.

Fig. 96.—EXAMPLES OF RATIOS OF STRESS AT THE TWO EDGES AND THE MEAN STRESS IN BASE OF RAIL TO THE AVERAGE MEAN STRESS ALONG THE TRACK.

The heavy line of Fig. 95, drawn through the points of mean stress in base of rail, may be considered as representative of the vertical bending moment developed in the rail from point to point. These mean stresses vary greatly from point to point along the track, being as much as 1.6 times the average stress along the track and at another place not far away only three-tenths of the average stress. That is, the mean stress in base of rail as measured on these stretches of track varied from .3 times the average stress along the track to 1.6 times the average stress, and this with the same load applied

in the same way. Doubtless wider extremes than these may frequently be found in track.

In Chapter VI "Tests of GEO Track on the Missouri Pacific Railroad", tests are reported on track which gave much greater uniformity in stresses in rail and in other ways. This GEO track has stiff tie-plates with the rail base fitting in closely between the two shoulders of the tie-plate and held to it tightly by bolts. A thin compressed wooden shim lies between the rail and the tie-plate. The ties were preadzed and pre-bored in such way as to make the base bearing of the two tie-plates on a tie fit the tie surface accurately and lie in the same plane, so that the rails will bear fully and uniformly on every tie-plate and that both rails will have the same cant. Likewise the rails were thus brought into proper gage when the screw spikes were applied and the wood under the tie-plate compressed somewhat by the spike tension. As stated in more detail in Chapter VI the roadbed was old and solid, the ballast (in some locations hard limestone and in others flint gravel) was of good depth and well distributed and consolidated, the ties were sound and straight and uniform in size and spacing, and the track in general excellent condition, though no maintenance had been given in the year it had been in service. The road was used principally for passenger service and the freight traffic had been light.

The measurement of stresses in base of rail at points between ties made on both rails at every other tie space for four test locations showed excellent uniformity and relatively little variation at the two edges of the base of rail for the four locations at which stresses were observed (see Table 28 and Fig. 78 and 79). In Fig. 96 are given for two locations the stresses in the two rails expressed in terms of the average stress along the track as unity. The variation of the stress at an edge of rail from the mean stress in the base for a given point is relatively very small and the freedom from lateral bending of rail correspondingly small (see Fig. 81 for plotted values of the lateral bending moments). The variation in mean stress and moment in rail from point to point along the track was also relatively small. Except for six places at which the two ties adjacent to the wheel had little play and the rail support was very stiff and where for two or three ties each way there was relatively more play, thus developing relatively small stresses and moments at the wheel, the variations in stress were small. Omitting the six low values, five places gave values 25 to 36 per cent greater than the average and two places 26 and 25 per cent less; the other 23 places gave an average variation from the average value of the mean stress of 13 per cent. For the fourth test location the variation was still less. Considering the natural variability of the track structure these results show exceptional uniformity of track.

The source of the variability in rail stresses along a track is evidently the variability in the rail support given by the substructure—in its stiffness in resisting pressure, in its position with respect to the rail, in the variation in vertical play between rail and ballast bed under the tie when load is applied which causes marked differences in the load carried by ties in the same group. The pull-up and push-down tests on the Chesapeake and Ohio Railway indicate great variations in load-taking characteristics at nearby ties because of the play between rail and tie and between tie and ballast bed (see Fig. 64, 65 and 66). The variation in rail depression as a wheel is moved from point to point along the track is quite marked, even though the rail acts to distribute the load over several ties (see Fig. 62 and 63). The examples of the division of load among a group of ties shown in Fig. 67 illustrates the great variability in load-carrying opportunity given to ties in track by moderate wheel loads—values ranging from zero to 2.5 times the average load. This variability is caused by what has been termed the varying play between the rail and its support. And these variations are found in track hav-

ing substantial stiff substructure considered to be in excellent condition. With such variations in the pressures both ties and ballast receive abnormal loads.

The variations in play between rail and tie bed found in the tests on the Missouri Pacific Railroad are smaller, even on the very stiff substructure, and the rail is correspondingly freer from marked changes in stress from point to point. However, the variation in vertical play between rail and ballast bed was sufficient to have caused considerable variation in the loads from tie to tie.

A principal source of the variation in stresses at the two edges of the base of rail from point to point as referred to above lies in the unevenness of the bearing of the rail on the tie-plate or of the tie-plate on the tie and even of the tie on its ballast bed. The unevenness may seem small but with the stiffness of the rail the varying position of the resultant of the tie reaction on the rail will result in lateral bending and twisting effects. Instead of the bearing pressure being uniform and the resultant of this pressure being at the center of rail base and width of tie, as indicated in the upper left corner of Fig. 97, the position of the resultant may be near one edge of the face of the tie (lower left corner of the figure), or the centroid of pressure may be at one side of the rail or the

Fig. 97.—DIAGRAM INDICATING VARIATIONS IN POSITION OF THE RESULTANT OF THE TIE REACTION ON THE RAIL.

other (right side of the figure), possibly with adjacent ties having conditions of bearings of opposite kinds thus concentrating vertical pressures first at one edge and then at the other edge of the rail. A gage the thickness of a piece of paper or even the blade of a shovel may be inserted at some spot under the rail or under the tie-plate and not elsewhere, so that with the stiff rail and a stiffly bedded tie the pressure will be concentrated near one edge of the rail. With the bending and twisting effect applied to the rail goes a corresponding eccentricity of pressure on tie and ballast which concentrates the load and otherwise produces undesirable distribution of pressures and contributes to an increase in maintenance costs.

The freedom from lateral bending and twisting in the rail on the track tested on the Missouri Pacific Railroad and the correspondingly even bearing of rail on tie may be accounted for principally by the method of machine adzing and boring the ties in such way that the plane of the base of both rails is made to coincide with the bearing plane of the tie-plate and the latter has an even and uniform bearing on the tie and is permanently held down firmly against the tie. A similar uniformity of action was observed in track having the tie-plates applied in a similar way on the Delaware, Lackawanna and Western Railroad in tests made in 1925 and 1926.

The variability found in the test stretches of the Chesapeake and Ohio Railway is not peculiar to this track—observations made on many railroads indicate that the same conditions exist quite generally—probably on most railroads. The tests call attention to the unfavorable effects of the variable conditions described.

An item not connected with the foregoing discussion may well be mentioned. Although the inclination of the tie-plates themselves was 1 in 28, observations made at 63 points along the stretch of track tested on the Chesapeake and Ohio Railway showed that the south rail had an average measured cant of 1 in 16 and the north rail 1 in 27, the cant for each rail being fairly uniform throughout. This difference in cant evidently caused the flange of the south wheels in moving along the track to hold closely to its rail (the one having the larger cant) and also gave direction to the lateral bending in the two rails. The two rails were on the same level.

**60. Influence of Strength and Stiffness of Rail and Stiffness and Uniformity of Substructure on the Quality and Stability of Track.**—The purpose of the tests made by the Committee in the nineteen years of its work has been not alone to determine how large are the stresses in rail and its depression in track; a main purpose has been to obtain data from which a study of track conditions and track properties may be made, to find the characteristics of the action of track of different kinds, to learn the cause of defects in track and the opportunities for improvement. A few words on the influence of strength and stiffness of rail and of stiffness and uniformity of substructure on the quality and stability of track based on the tests and the analysis may be useful as having a bearing on discussions of track. It will be recalled that the tests have included rails from 56- to 136-lb. per yd. and stiffnesses of rail support with values of  $u$  from 500 to 6000.

In the previous discussions the part of the track below the rail has generally been referred to as the "rail support", especially in connection with the values of depression and moments in the rail. In connection with discussions on effects produced by track depression and moments in the rail and possible movements of the tie and of the ballast which may influence maintenance, the term "substructure" is used to include all the supporting structure below the rail. The two terms then refer to the same part of the track.

### 1. Size of Rail.

(a) *Moments and Stresses.*—It has been found that the moment developed in the rail by a single wheel load is dependent upon the stiffness of the rail and the stiffness of the rail support. For the single wheel load the moment ( $M_o$ ) developed in 152-lb. rail averages 1.36 times that in a 90-lb. rail when  $u$  lies between 1000 and 6000 (see Table 31). The single trailer placed at some distance from the driving wheels and other wheels of a locomotive gives the nearest approach to a single wheel load; the moment  $M_T$  at the trailer of the Mikado locomotive of Table 32 and  $u$  of 1000 is almost the same with every weight of rail, while with  $u$  of 6000 the moment for 152-lb. rail is 1.26 times that for 90-lb. rail. The moment developed at the fourth driving wheel of the Mikado locomotive with a given value of  $u$  does not differ greatly for the several rail sections, the increase in the moment developed in the 152-lb. rail over that in the 90-lb. rail ranging from nothing at  $u$  of 1000 to 14 per cent at  $u$  of 6000. The moment developed in 152-lb. rail at an end wheel of the group of wheels of two coupled car wheels (the wheel developing the greatest moment in the rail) is about 25 per cent greater than that developed in 90-lb. rail (see Table 33). For any given moment the stresses in rail will

of course be inversely proportional to the section modulus of the rail section. Although no limiting rail stress may well be set without specifying the nature of the track and rolling stock and other conditions, it may be said for track in good condition and for the more common wheel loads and speeds and proper conditions of rolling stock that the longitudinal bending stresses in the medium weights of rail (say from 90- to 112-lb. sections) will not be excessive for ordinarily closely spaced groups of wheels. The lateral bending strength of the rail is also ample to resist the lateral moments ordinarily applied by side thrusts. The principal advantage of the heavier rail sections must then lie in other directions than longitudinal bending strength.

(b) *Wheel Bearing Pressure.*—Tests have not been made in this work to determine the effect of size of rail head and web upon the resistance to the bearing pressures of wheels. It is evident that a great variety of the worn contours of wheels and rails would be involved in any comprehensive tests. Nor has it been considered within the scope of the work to learn the relation between such pressures and such contours and the formation or extension of flaws or nuclei conducive to rail failure. Important as such information is, an investigation would need lines of attack different from those available to the Committee.

(c) *Tipping Stresses.*—The investigation has not given attention to the needs of the rail in resisting bending of the rail section upon itself laterally and the strength of the web and the base needed to resist the forces that act when the resultant of the supporting pressure at the bottom of the loaded rail has a position at or near one edge of the base of rail. This situation may exist when a wheel applies a large lateral thrust. It may also occur when the rail and tie-plate bearing is out-of-plane with the base of rail, and the difficulty may be aggravated when the out-of-planeness is in opposite directions at nearby ties. Frozen or unevenly thawed substructure or "heaved" track subjects the rail to abnormal conditions in these respects. In well ballasted and well surfaced track, particularly when the bearings of the tie-plate are in plane with the base of rail and when moderate lateral thrusts are applied by the wheels, the tipping moment generally will be readily resisted. Where large lateral forces are applied or where unfavorable track conditions such as those referred to above exist, high stresses and pressures will be developed, especially with the lighter rail sections.

(d) *Rail Stiffness.*—The greater stiffness of a heavier rail section has frequently been considered of value as carrying the load farther ahead or behind the wheel. This characteristic is related to stiffness of rail support, and the magnitude of  $u$  affects their relations in such a way that the influence of a heavier rail in giving any extension of support in front or back of a group of ordinarily closely spaced wheels has been found to be small. Besides, the average tie pressure at points between the front and back wheels of a group of ordinarily closely spaced wheels has been found not to differ much throughout the range of rail sections considered. In some respects the heavier sections have disadvantages in that they do not bend and twist and adjust themselves into new positions to fit abnormal conditions of track as much as the lighter sections may. It will be seen from the relative rail depressions that the greater stiffness of a heavier rail does not greatly affect the springiness or the resiliency of the track in taking sudden changes of load applied through defective rolling stock or the abnormal dynamic augmentation of an imperfect counterbalance. It is the stiffness of the substructure that mostly governs the springiness of track under a group of wheels, though the stiffness of the rail will take a local part in the spring, particularly when the increased load is on only

one wheel, as with dynamic augment of the main driving wheel. However, other advantages which accrue with the added stiffness of rail give value to the heavier sections.

(e) *Stability of Rail*.—The greatest value of heavier rail may be said to be the greater stability it gives to track. Stability implies the ability to maintain favorable conditions, to resist unusual or unexpected forces or loads, to overcome the variations. The greater stiffness of a heavier section aids in carrying loads over imperfectly tamped track and irregular supports; it resists lateral thrusts and lurches without undue distortion of alignment; it aids in maintaining proper surface. Even the added mass of the heavier rail is an element of stability. The added stiffness should be considered a help in reducing cost of maintenance.

It may be added that the value of increased size of rail will depend upon many circumstances, among them amount and nature of traffic, nature of substructure, wheel loads and speeds, and any economies involved in the situation. It is not to be expected that this value can be expressed quantitatively in formulas or equations, but studies of accompanying conditions should be helpful in forming a judgment.

## 2. Stiffness and Uniformity of Substructure.

(i) *Effect on Moment and Stress in Rail*.—As stated in Article 57 "Relations of Rail Properties, Rail-Support Stiffness and Wheel Spacing to Rail Stress, Moment and Depression and to Tie Load and Other Matters that Influence the Durability and Up-keep of Track", the moment developed in a given rail under a single wheel load is decreased considerably with increased stiffness of the substructure using the term substructure to include everything below the rail. In Table 31, the moment developed by a single wheel load when  $u$  is 6000 is .64 times that when  $u$  is 1000 for both the 90-lb. and the 152-lb. rail. For the trailer (the wheel having spacing conditions approaching those of a single wheel) the moment ( $M_T$ ) (see Table 32) with  $u$  of 6000 is .74 times that with  $u$  of 1000 for 90-lb. rail, and the corresponding ratio for 152-lb. rail is .94. For the fourth driving wheel of the Mikado type locomotive ( $M_4$ ), however, the effect of increasing the stiffness of the rail support is much less, the corresponding ratio of moments for 90-lb. rail being .86 and for 152-lb. rail .98. Somewhat similar ratios exist for the group of wheels of coupled cars. It may be said then that increased stiffness of rail support has relatively little effect on the moment in a given rail developed by one of a group of closely spaced wheels, but that the moment at the trailer may have considerable decrease in the case of the lighter rail sections. As the stress in a given rail is proportional to the moment developed, the conclusion given for moments may be applied to stresses.

(g) *Effect on Track Depression and Tie Load*.—For a group of wheels of ordinarily close spacing, the maximum depression of rail at a wheel may be said to vary nearly inversely as the stiffness of the rail support. For the Mikado type locomotive (see Table 34), the rail depression at the main driver ( $y_3$ ) (the one giving the greatest depression) for the rail sections used is about 3 per cent greater at  $u$  of 6000 than the value found by taking one-sixth of the depression for the same rail at  $u$  of 1000. The maximum rail depression at a wheel of the trucks of two coupled coal cars given in Table 35 for  $u$  of 6000 is only slightly greater than the value found by taking one-sixth of the maximum depression at a wheel at  $u$  of 1000 for any of the rail sections. If the comparison had been made between moduli of 1500 and 3000 (a more usual range in stiffness) the agreement would have been closer. For many purposes then the maximum depression at the wheels of a group may be considered to be approximately inversely proportional to the stiffness of the substructure regardless of the weight of the rail.

The changes in tie pressure due to differences in stiffness of substructure on good track that is relatively free from play between rail and tie bed may be compared by using the rail depressions given by the analysis and the corresponding vertical pressure applied by the rail per inch of length of rail. It may then be considered that the tie pressure at any point is proportional to the product of the rail depression and the modulus  $u$  ( $p = -uy$ , equation (6)). For a group of ordinarily closely spaced wheels on high-grade track there will not be large differences in the magnitudes of the tie pressures at a given point between the end wheels of the group regardless of the stiffness of the track. For the Mikado locomotive of Table 34, it will be seen by multiplying  $y_3$  by  $u$  that with all rail sections and all values of  $u$  the vertical pressure of the rail at the main driving wheel (the wheel having the greatest depression) does not vary much from 500 lb. per inch of length of rail. For the truck wheels of the two coupled cars of Table 35, by the same procedure it is found that with 90-lb. rail the maximum pressure under a wheel (either an end wheel of the group or an interior wheel) ranges from 360 lb. per in. for  $u$  of 1000 to 420 lb. per in. for  $u$  of 6000, while for the heavier rail sections the change is much less. However, when the pressures at the wheels and at a point between wheels along the distance between the end wheels of the group are averaged, the magnitudes of the average pressure vary but little through the range of  $u$  for any of the rail sections, even for all the sections and all the values of  $u$ . An approximate average value of the load on an individual tie at a given wheel may be found by multiplying the intensity ( $p$ ) of the vertical pressure used above by the spacing of the ties center to center. Variations will be found for other types of locomotives and cars. For the usual types with ordinarily closely spaced wheels, however, for purposes of general comparison of tie loads it may be considered for track having only slight variation in play between rail and tie bed that the average tie load or even the maximum tie load under a given group of wheel loads will not vary greatly with different rail sections and differences in stiffness of rail support within the ranges here considered.

(h) *Effect of Springiness of Substructure.*—In Table 34 it will be seen that under the loading of this Mikado locomotive the maximum depression of the rail for the several values of  $u$  ranges from .47 to .08 in. The vertical travel of the springiness of the substructure under load for different values of  $u$  may be considered to vary fairly proportionately throughout this range. It is obvious that the greater vertical travel of the rail for the lesser stiffness may result in a smaller additional wheel pressure on the rail when acting to reduce longitudinal teetering of locomotives and cars and similar movements. On the other hand the smaller travel of the stiffer track is advantageous in damping direct vertical vibrations of cars. It will better take the unsprung load due to the dynamic augment of imperfect counterbalancing and also will not permit the locomotive itself to move downward through an appreciable distance during the application of this changing pressure. For rough track (considering the variations from a regular surface and alignment to be equal in the two cases) the stiffer track will better damp the vertical and lateral oscillations of the cars. Probably too it will better resist the forces applied by the imperfections of rolling stock.

(i) *Effect on Variability in Stress in Rail and on Irregularities in Rail Support.*—Tests on what is usually considered good track, such as those described in Chapter V, have shown marked variations in the play between rail and tie bed as the load comes on the track. This variability is relatively much greater with stiff substructure than with less stiff track equally well kept up. On stiff substructure the mean stress in base of rail has been found under static loading to vary from one-tenth of the average stress

along the rail to 1.75 times. The load carried by an individual tie has varied from nothing to 2.7 times the average tie load for the moderate wheel loads. Similar variations exist in the loads carried by the ballast. Doubtless much greater variations than those reported exist in track. This variability of distribution, of course, puts undue and irregular demands upon the substructure and adversely affects its durability and the cost of its maintenance. It is a prolific source of deterioration in track condition. Any approach toward uniformity in stiffness of substructure and freedom from uneven play between rail and tie support will result in an item in the economics of track maintenance worth consideration. That unevenness of support has been found to produce stress at one edge of base of rail nearly three times as great as the average mean stress should also be remembered.

In this connection it may be noted that variations in the application of the wheel load to the rail and the variable effects of speed will give still greater variability in the stresses in rail, both because of defects of the rolling stock and because of the effect of speed on the conditions here discussed.

(j) *Effect on Stability of Substructure.*—It is to be expected that the stiffness of the substructure in general will affect its stability and durability under traffic. The elements that go to make up stiffness or lack of stiffness in the substructure also affect the resistance or lack of resistance to heavy loads and to movements within the substructure. The less stiff substructure is more susceptible to injury, especially under heavy loads repeatedly applied. The action accompanying the greater vertical movements of the rail is more destructive of uniformity and stability in the track as a whole. The imperfect bearing of tie-plate on tie concentrates pressures on small areas and produces greater compressions and detrusions into the wood. The unevenness of bearing of tie on ballast (either in a direction across or along the tie, not considering the middle part of the tie length) also increases the concentration of pressure on the ballast and even the detrusion. Even the greater individual loads found at individual ties along the track increase the general depression of the rail over that obtaining with more nearly uniform distribution. The nature of the material forming the ballast necessarily affects the stiffness; and particles of such smoothness or softness and such size or gradation as to move easily on one another give greater depression. Qualities affecting stability show themselves in other ways.

It is also apparent that the magnitude of the vertical movements affects the stability and durability of substructure under heavy traffic. A substructure whose make-up permits large vertical movement under a given tie load does not have the qualities to resist deterioration of structure and especially unevenness of deterioration. The action of a substructure that gives a vertical depression of .4 in. may be expected to give way under the application of millions of groups of car wheels and a corresponding number of ups and downs, where one giving a depression of .1 or .2 in. will remain in fair condition. This is especially true in certain parts of the substructure. In other words, the conclusions of experience with different track substructures are borne out by an examination of the loads and conditions to which they are subject.

Still another way of considering the value of stiffness and stability of the part of the track below the rail may well be mentioned. In a substructure of low stiffness (small value of  $u$ ), a part of the greater depression under load, as compared with stiffer substructure, is due to uneven bearing over the tie-plate and to the greater detrusion or compression of the tie caused by this concentration of pressure and to flexure of tie before the tie reaches its bed along its length and a part is due to the variation in pressure

from tie to tie due to differences in play between rail and tie and tie and its bed. Another part of the remainder is due to the lack of uniformity of distribution of pressures below the ballast along the track. With a low modulus, especially with a shallow depth of ballast or with unconsolidated ballast, the pressures on the roadbed under the ballast at a tie may be much greater than those between ties, so that a greater compression of ballast and roadbed will occur than for uniformly distributed pressures. Besides, the concentrations of pressure at certain points may exceed the permanent resistance of the material to repeated application of pressures, resulting in uneven movement of the particles over one another. The effects may be expected to be related to the magnitudes of the depression and to the energy applied to the substructure. The loss of applied energy through slight inelastic movements of particles among themselves and by abrasion and consolidation may increase the variability of the distribution of pressures on the ballast and roadbed along the track. These effects will be influenced by the magnitude of the track depression.

Since the pressures on the ties produced by a group of wheels carrying given loads are approximately the same regardless of the value of  $u$  and the size of the rail section, and since the energy put into the depression of the rail and the substructure by the load of the group of wheels may be considered to be equal to one half of the product of  $u$  and the average rail depression multiplied by the length of rail depressed, the energy so exerted may be said roughly to be inversely proportional to the value of  $u$ . With  $u$  of 3000, half as much energy then is applied to the rail and ties and ballast as with  $u$  of 1500. As the loss of energy and the injury to track through movement among the parts and the particles may be expected to vary in some way with the amount of the energy applied to the structure, less injury is given to line, surface, and uniformity of track when the substructure is stiff than when it lacks requisite stiffness. This is only another way of coming to the conclusion that, granting other requisites such as smoothness and uniformity of track, the stiff rail support has advantages in matters of maintenance, durability and stability, which are highly worthy of consideration.

**61. Advantages of High Grade Track.**—In Article 57 "Uniformity and Variability in Track"\* of the Fifth Progress Report the need for uniformity in elasticity and stiffness of the rail support in track was discussed and the disadvantages of variability in the supporting resistance were considered. The tests described in the present report furnish further important data on the effects of variability on the action of the track and its resistance to the variable loads applied under traffic conditions. They throw light on the elements that will aid in prolonging the life of track and decreasing the expense of maintenance. The elements entering into the advantages of high-grade track are mostly obvious, but for helping to keep in mind their nature and value it may be well to repeat statements about some of them.

Regardless of sufficiency of strength in a rail the greater stiffness of the heavier rail is useful in reducing the twisting movement of the rail and in distributing the variable effects of this twisting over the ties; it thus gives more nearly vertical loads on ties that have uneven support along their length or width or otherwise have irregular supports. The stability of track given by the heavier rail is an element of value that should receive full consideration. The greater reserve capacity against unexpected and excessive variability in the loads applied and the improvement in the support afforded are of real value.

\* Proceedings, A.R.E.A., Vol. 31 (1930), p. 325.

Giving the rail an inclination from the vertical inwardly of the track has been found to improve the bearing of wheel on rail and to give a better distribution of the stresses through the rail section to the tie-plate. An inclination of 1 in 20 best fits the standard coning of wheels. However, the use of 1 in 40 has been found to give advantages over a vertical position.

Evenness of bearing of rail on tie-plate and of tie-plate on tie is a most important element in giving quality and stability to track. Unevenness of bearing, out-of-planeness with the bases of the two rails, and eccentric position of the resultant of the bearing pressure have marked influence on stresses in rail, deterioration of tie wood, and concentrations of bearing pressure on the ballast bed of the tie. Even apparently small variations in bearings may give troublesome results. Uniformity in dimensions of ties and reasonable straightness are elements of importance. Obviously adequate and uniform bearing bed on the ballast is an essential to uniformity of support. Solidity and uniformity of roadbed of course are assumed.

Uneven play between rail and tie bed at nearby ties results in irregularities in the stresses in the rail and likewise in the loads carried by individual ties. The high tie must be depressed before the remaining ties take load, and under the full loads of a group of wheels the higher ties will carry a larger share of the load than will those that were the lower ones. With a stiff ballast bed traffic will not permanently depress the high ties to give uniform bearing. As a result of the variability of the bearing surface, some ties may carry no load and others two or more times the average load. Observations on track show that as the stiffness of the track substructure has been increased in recent years and the rail support given greater solidity and stiffness the magnitude of the variability of this play between rail and tie bed in ordinarily well-kept track has not changed much. The unloaded rail may rest on four or five ties in a rail length and the varying play referred to may be .05 in. or .10 in. or even more. In a track with stiff substructure the resulting variation in load will have a greater proportionate effect than in a less stiff track. For a track developing a net rail depression of .40 in. under a group of given wheel loads, an unevenness of play of .10 in. may result in a range of tie load perhaps from .75 to 1.25 times the average load. With a stiffer substructure and the same unevenness of play, one having an average net depression of .10 in. under the same load, the variation in tie load would be greater, ranging from 0 to 2.0 times the average load or more. A corresponding variation in stress in rail and other demands on the track will also be found.

It is evident that the greater stiffness in track substructure obtained in recent years contributes to a greater variability in moments and stresses in rail and in the distribution in tie and ballast loads in what is considered well-kept track. All observations emphasize the need and the value of exercising great care in obtaining reasonable uniformity in the condition of the substructure of track. It is apparent that new and better means should be devised for ensuring absence of variations in play between rail and tie bed and for securing uniformity of stiffness in the tie and ballast support. The call for improvement in uniformity applies to both medium and heavy rail, and should not be neglected even with light rail.

Machine tamping without proper control will fail to produce reasonable uniformity. Irregular play between rail and tie bed may soon develop in the track under usual conditions of tamping. To meet this difficulty new and better means should be devised to

know when adjacent ties or groups of ties are evenly tamped, and ways should be provided for checking results of maintenance work. The track should be put in such condition that each tie will carry its share of load. It should become an accepted principle of practice that absence of variability is a test of workmanlike maintenance.

The effectiveness of deep, consolidated ballast in distributing load and in minimizing the consequences of imperfect conditions in the track above it was referred to in the Fifth Progress Report as an element of financial value in the maintenance of track. Adequate depth and solidity are instrumental in providing uniformity of resistance both at a local group of ties and between one group and another some distance away. The thick bed of consolidated ballast in some ways acts somewhat like a beam and thus aids in providing stability and uniformity (see Fifth Progress Report, Proceedings, A.R.E.A., Vol. 31 (1930), page 327).

It is usually accepted that smoothness of track is a desideratum. The efforts toward gaining and maintaining uniformity of track under load herein suggested are steps toward improving smoothness. It is obvious that smoothness of track helps to reduce the forces and blows applied by rolling stock (whether the rolling stock is in good condition or poor) and thus in this way the needs for maintenance are decreased. Any improvement which reduces variations in line and surface existing under train loads not only gives more uniform stresses and pressures on rail and tie and ballast, as heretofore described, but it aids in producing a more nearly uniform straight-forward motion of the wheels along the track (reducing the side-to-side movement of the cars with flanges of wheels first against one rail and then against the other and decreasing the resulting frictional movement of both flanges and treads) and thus reduces wear of rail and variation of pressure on tie and ballast—at the same time giving relief from similar troubles in the rolling stock itself. Similarly, the tractive resistance caused by uneven or irregular action of the rolling stock may be expected to be lessened somewhat over that of less smooth track, though except when compared with rough track this effect will be small in proportion to the total resistance, for the journal friction and the air and wind resistances constitute by far the largest part of train resistance.

The higher speeds now demanded for both passenger and freight trains require uniformity of surface under load for longer distances along a track. The vertical and horizontal oscillations of locomotives and cars generally have nearly the same period of oscillation for different speeds, and for the high speeds uniformity is therefore needed over long stretches of track. This need as well as the possible cumulative effect of local variations puts more severe demands on high-speed track in a number of ways than are found for slower speeds.

In a general way there is mutuality in the effect of the condition of the track and rolling stock which should be recognized—that which injuriously affects one may have a similar effect on the other. Roughness of loaded track in line and surface increases wear and maintenance of rolling stock as well as track, and imperfections of wheels and trucks and running gear and attachments to body that may interfere with straight-forward motion and uniformity of wheel load will influence the wear of both cars and track. On the other hand, such matters as out-of-roundness of wheels and the dynamic augment of unbalanced rotating parts may have a far more detrimental effect on the track than on the rolling stock. However, the interrelation of the track and the rolling stock is of paramount interest and should always receive adequate consideration.

The discussions of this chapter are intended to apply particularly to straight track. Although curved track has many special characteristics and requirements, much of the discussion it will be seen also applies to the curved track.

Finally, it may be said that the advantages and necessities for high-grade track are such as to warrant a more thorough study of the elements entering into its construction and maintenance and the means of obtaining it easily and economically.

Respectfully submitted,

THE SPECIAL COMMITTEE ON STRESSES IN RAILROAD TRACK,

A. N. TALBOT, *Chairman.*

## REPORT OF COMMITTEE XX—UNIFORM GENERAL CONTRACT FORMS

F. L. NICHOLSON, *Chairman*; B. HERMAN,  
C. FRANK ALLEN, J. C. IRWIN,  
E. H. BARNHART, A. C. JACKSON,  
W. H. BRAMELD, J. S. LILLIE,  
B. S. DICKERSON, S. L. MAPES,  
R. P. EUBANK, A. A. MILLER,  
W. D. FAUCETTE, O. K. MORGAN,  
F. H. FECHTIG, C. B. NIEHAUS,  
J. P. HANLEY, H. A. PALMER,

W. G. NUSZ, *Vice-Chairman*;  
W. M. POST,  
J. A. RUSSELL,  
CHAS. SILLIMAN,  
HUNTINGTON SMITH,  
W. R. SWATOSH,  
J. S. THORP,  
C. A. WILSON,  
*Committee.*

*To the American Railway Engineering Association:*

Your Committee respectfully reports on the following subjects:

1. Revision of Manual—Appendix A.

The Committee has no revisions to recommend.

2. Form of Agreement for the Purchase of Electrical Energy in Large Volume (such as required for traction purposes), collaborating with Electrical Section—Appendix B:

This subject was assigned in 1928, and in the preparation of this Form of Agreement, the Committee has had the valuable and whole-hearted collaboration of the Electrical Section, through a sub-committee appointed for the purpose; authorities both from the production or selling side and the using or purchasing side, have been consulted and many suggestions have been received influencing the terms and conditions as written in the completed form now presented for adoption as Recommended Practice and for printing in the Manual.

3. Form of Conveyance of Title Granting the Right to Construct and Maintain Buildings over Railway Property—Appendix C:

This form has been very carefully prepared after studying all available contracts and conveyances and is submitted as information with the hope that members interested in the subject will carefully review and give the benefit of their views to the Committee.

It is recommended that the subject be continued.

4. Form of Agreement for Pipe Line Crossings under Railway Tracks—Appendix D; and

5. Form of Agreement for Use of Railway Property by Pipe Lines paralleling Railway, with Special Reference to Pipe Lines Carrying High Pressure Inflammable Oils or Gas, collaborating with Committee I—Roadway and Committee XIII—Water Service and Sanitation, Appendix D:

When the Committee began preparation of these forms, it came to the conclusion that one form could be prepared to cover both assignments, and the form now presented has been prepared in collaboration with Committee I—Roadway and Committee XIII—Water Service and Sanitation, and after several conferences with special committees of the American Petroleum Institute.

This Form is presented for adoption as Recommended Practice and for printing in the Manual.

6. Form of Agreement with Public Authorities for Highway Grade Crossing Elimination or Separation, collaborating with Committee IX—Grade Crossings—Appendix E:

This Form of Agreement as prepared and submitted, covering both over and under pass grade separation, is very complete and worthy of your acceptance, but, following the practice of the Committee to give ample opportunity for discussion and suggestions, it is submitted as a progress report with the hope that the members will favor the Committee with such suggestions as they care to make for its betterment, that the Committee may present at the next convention for adoption, a form that will be most useful to you.

It is recommended that the subject be continued.

Respectfully submitted,

THE COMMITTEE ON UNIFORM GENERAL CONTRACT FORMS,

F. L. NICHOLSON, *Chairman.*

## Appendix A

### (1) REVISION OF MANUAL

C. A. Wilson, Chairman, Sub-Committee; C. Frank Allen, R. P. Eubank, J. C. Irwin, J. S. Lillie, A. A. Miller, W. G. Nusz.

Your Committee has no revisions to recommend at this time.

## Appendix B

### (2) FORM OF AGREEMENT FOR THE PURCHASE OF ELECTRICAL ENERGY IN LARGE VOLUME (SUCH AS REQUIRED FOR TRACTION PURPOSES)

W. G. Nusz, Chairman, Sub-Committee; W. H. Brameld, S. L. Mapes, W. M. Post and J. S. Thorp.

Your Committee presented a preliminary draft of the Form of Agreement for the Purchase of Electrical Energy in Large Volume in 1932, Bulletin 340. A joint meeting of the Sub-Committee of Committee XX and a Sub-Committee of Committee XVII of the Electrical Section, held this year, considered all of the comments and suggestions received and your Committee now submits a draft of the completed Form of Agreement and recommends its adoption as recommended practice and that it be printed in the Manual.

| Section 6. Termination by Power Company for Interference to Its Service to<br>Other Customers..... | 317  |
| Article IX—Reduction in Rates.....                                                                 | 317  |
| Article X—Arbitration .....                                                                        | 318  |
| Article XI—General .....                                                                           | 318  |
| Section 1. Right of Access to Railway Company Property.....                                        | 318  |
| Section 2. Repair and Renewal of Apparatus.....                                                    | 318  |
| Section 3. Indemnity Clauses .....                                                                 | 319  |
| Section 4. Waivers .....                                                                           | 319  |
| Section 5. Assignment .....                                                                        | 319  |

### FORM OF AGREEMENT FOR PURCHASE OF ELECTRICAL ENERGY IN LARGE VOLUME (SUCH AS REQUIRED FOR TRACTION PURPOSES)

THIS AGREEMENT, made this ..... day of .....,  
 19.... by and between.....,  
 a corporation organized and existing under the laws of the State of.....,  
 hereinafter called the "Power Company", and.....,  
 a corporation organized and existing under the laws of the State of.....,  
 hereinafter called the "Railway Company".

#### WITNESSETH:

WHEREAS, the Railway Company desires to purchase and take from the Power  
 Company and the Power Company desires to sell and deliver to the Railway Company,

during the term hereof, electric energy (hereinafter called "energy") estimated to be initially about.....kilowatts of Billing Demand (as hereinafter defined) for electric operation of certain portions of the Railway Company's system comprising ..... all of which lines are located as shown on map dated....., designated....., marked "Appendix A", attached hereto and made a part hereof, and for other purposes as hereinafter provided.

NOW, THEREFORE, in consideration of the covenants and agreements herein contained, to be performed by the parties hereto and of the payments hereinafter agreed to be made, it is mutually agreed as follows:

## ARTICLE I

### TERM OF AGREEMENT

The term of this agreement shall be..... (.....) years, commencing on....., or on such earlier date as the Railway Company may designate by written notice to the Power Company at least..... (.....) months prior to such earlier date; subject, however, to termination as provided in Article VIII.

The Railway Company shall have the right, at its option, to extend the original term hereof for a period of.....years by giving to the Power Company not later than.....months prior to the expiration of the original term, written notice of its election to make such extension.

## ARTICLE II

### OBLIGATIONS AS TO SUPPLY AND PURCHASE

For and during the term hereof the Power Company shall supply and deliver, and the Railway Company shall purchase and take from the Power Company, in accordance with and subject to the terms, provisions and conditions herein contained, the energy used within the territory hereinbefore defined, for or in connection with the electric operation of trains and for non-traction purposes connected with or incidental to the construction, maintenance, use and operation of the Railway Company's properties, whether occupied or used by it as a common carrier or otherwise, or leased or sub-leased to tenants or sub-tenants; provided, however, that;

(Insert here the provisions as to proportion of requirements to be supplied; resale; limits of supply to tenants; generation at existing Railway Company plants; supply to other railways using the Railway Company's tracks; regeneration; increasing demands; and other provisions of special nature).

In the event of failure of the Power Company's supply of energy, the Railway Company shall have the right to use during such failure for any purpose energy acquired from any other available source.

Incidental flow of energy through the Railway Company's circuits from other power sources shall not be considered contrary to the intent of this article.

## ARTICLE III

## CHARACTER OF SERVICE

The energy to be supplied hereunder shall be in the form of.....  
.....phase, .....wire, .....cycle,  
alternating current and at a normal voltage of.....volts per  
phase and/or direct current at a normal voltage of.....volts  
and at other voltages, frequencies or number of phases agreed upon by the parties hereto.

The frequency and voltage at the points of delivery shall be as constant as practicable, considering the characteristics of the Railway Company's load and the operating requirements of the Power Company's system.

Under normal conditions of operation on the Railway Company's system and on the Power Company's system, the voltage variation at the points of delivery shall not exceed  
.....per cent (.....%) above or below the normal voltage.

## ARTICLE IV

## CHARACTER OF LOAD

The type, arrangement and operation of the equipment used by the Railway Company in connection with the energy taken hereunder shall be such as will not materially interfere with the operation of the Power Company's system and service to its other customers.

The power factor of the Railway Company's system during periods of heavy demand shall not be less than.....per cent (.....%) lagging.

## ARTICLE V

## POINTS OF DELIVERY

The energy to be supplied hereunder shall be delivered by the Power Company to the Railway Company and measured at the following points:

(Railway Sub-stations, Power Company Generating Stations, Power Company Sub-stations, etc. Specify method of connection and division of ownership, operation and maintenance of facilities.)

## ARTICLE VI

## RATES AND PAYMENTS

Section 1. For each calendar month of the term hereof, the Railway Company shall pay to the Power Company the following:

(a) An amount of money known as the Primary Charge equal to.....  
.....dollars (\$.....) per kilowatt of Billing Demand for that month. Such Billing Demand shall be the Maximum Demand for the month ascertained in accordance with Section 2 of this Article, or.....per cent  
(.....%) of the greatest previous maximum demand during the last preceding twelve months or.....kilowatts whichever is the greatest; provided, however, that the Billing Demand for each month during the first year of said term shall be the actual Maximum Demand for that month and the Maximum Demand for each such month shall be ignored in determining the Billing Demand for any subsequent month, and further provided that the sum of the Primary Charges for the first year of said term shall not be less than.....dollars (\$.....).

(b) An amount of money known as the Secondary Charge, equal to..... mills (\$.....) per kilowatt hour of energy furnished hereunder during each month, subject to the addition or deduction of...../1000ths of a mill (\$.....) per kilowatt hour for each.....cents (.....¢) of increase or decrease from the average delivered cost per unit of fuel of..... dollars (\$.....).

(Note:—It may be desirable to have either or both the Primary and Secondary Charges in blocks. Also, consideration should be given to the effect of variations in labor costs and to the variations in cost per kilowatt hour at switchboard of hydro-electric plants.)

The number of kilowatt hours to be used in computing the Secondary Charge for any month shall not be less than.....per cent (.....%) of the equivalent of the Billing Demand for such month if used during each and every hour of that month.

Section 2. As soon as practicable after the end of each calendar month the Railway Company's Maximum Demand in kilowatts for such month shall be ascertained as follows:

From each of three days in the month there shall be selected one even clock hour which shall be the hour of greatest combined draft of the day from which it is taken; and said three days shall be such that the sum of the combined drafts of the three hours selected therefrom in the manner thus indicated shall be greater than the sum of the combined drafts of three hours similarly selected from any other three days in the month. One-third of the sum of the combined drafts of the three hours selected as aforesaid from each month shall be taken and considered as the number of kilowatts constituting the Maximum Demand.

Said combined draft during any even clock hour shall be the amount of energy measured in kilowatt hours, or shall be.....per cent (.....%) of the resultant integrated product of voltage and current, measured in kilovolt-ampere hours, whichever shall be greater, and shall be construed as representing a single quantity of energy, or.....per cent (.....%) of the resultant integrated product of voltage and current, as the case may be, taken hereunder at the several points of delivery just as though the various quantities were measured and integrated as one quantity at one point.

Maximum Demands occurring on Sundays, legal holidays, between noon and 11:00 o'clock on Saturdays, and between 11:00 o'clock any evening and 6:00 o'clock the following morning shall be ignored in determining the Billing Demand for any month.

If in any month the Railway Company shall require an abnormal energy supply caused by excessive or congested traffic beyond that usually handled by the Railway Company or due to storm, accident, complete or partial failure of the Power Company's supply of energy, derangement of the Railway Company's power facilities, or any other emergency condition, the Power Company will, if it has sufficient capacity available at the time, supply such abnormal demand, provided the Railway Company shall give the Power Company prompt notice of such abnormal demand by telephone or otherwise, confirming such notice by letter within forty-eight (48) hours. The Railway Company agrees, however, to promptly reduce the demand to normal upon notification from the Power Company that such reduction is necessary to preserve the general service of the Power Company. In ascertaining the Maximum Demand for such months, hours, in which such abnormal demand or demands occur shall not be selected unless such abnormal demands occur in.....or more consecutive days; and in

the latter event, hours in which such abnormal demands occur may be selected from any of such consecutive days following the.....of such consecutive days, but such hours shall be ignored in determining the Billing Demand for any month subsequent to the month in which such abnormal demand occurred and shall be ignored in determining the minimum number of kilowatt hours to be used in computing the Secondary Charge for that month.

Section 3. The Railway Company shall have the right at all reasonable times to examine and make copies of all meter and other records of the Power Company used in the computation of bills rendered hereunder.

Section 4. All payments for charges incurred under the provisions of this agreement during any calendar month shall be due and payable..... (.....) days after receipt of the bill therefor.

In case payment of a charge be not made on or before the day upon which it becomes due, interest shall accrue upon such charge at the rate of..... per cent (.....%) per annum from the date on which it becomes due. In case the Railway Company questions the correctness of any bill it shall nevertheless make payment of the full amount thereof. When decision or agreement with respect to the questioned bill is reached, the Power Company shall refund the overpayment, if any, together with interest thereon at the rate of.....per cent (.....%) per annum from the date on which such bill was originally paid.

## ARTICLE VII

### METERING

Section 1. All energy furnished under this agreement shall be measured at the points of delivery by meters to be installed and maintained by the Power Company at its expense.

Section 2. The instruments to be installed by the Power Company shall be of a standard type and manufacture and shall accurately measure the energy in electric units and periods of time as required by the terms of this agreement. The Railway Company shall have the right to be represented at the readings of these instruments and at the testing, adjusting or changing thereof.

Section 3. All meters shall be tested and calibrated by the Power Company every .....by comparison with accurate standards, and if as the result of any test a meter shall be found to be inaccurate, it shall be restored to an accurate condition or an accurate meter shall be substituted by the Power Company. Either party to this agreement shall have the right to require that a test be made of any meter at any time. The party desiring such test shall make request therefor in writing upon the other party and thereupon such meter shall be tested and calibrated by the Power Company, and if it shall be found inaccurate it shall be restored to an accurate condition or an accurate meter shall be substituted by the Power Company. If as a result of any test any meter shall be found to register in excess of two per cent (2%) either above or below normal, then the readings of such meter previously taken shall be corrected, but no such correction, either in respect to demand or kilowatt hours drawn or consumed, shall extend back beyond thirty (30) days previous to the date on which such inaccuracy shall be discovered by such test, and if during such previous thirty (30) days one or more prior tests shall have been made under the provisions hereof, then no such correction shall extend back beyond the date of the last of such prior tests.

The Power Company shall give to the Railway Company reasonable notice of the time when any test will be made as hereinbefore provided.

If any special test of any meter shall be made at the request of the Railway Company with the result that such meter shall be found to register correctly or within two per cent (2%) of normal, then the Railway Company shall bear the expense of such test. The expense of all other tests shall be borne by the Power Company.

#### ARTICLE VIII

#### INTERRUPTION, DEFAULT AND TERMINATION

Section 1. The Power Company shall use all due diligence in providing a regular and uninterrupted supply of energy, but in case the supply of energy shall be interrupted, be defective or fail for any cause, the Power Company shall not be liable therefor, except as otherwise herein provided.

If, however, such failure occur, the Railway Company shall be entitled to a proportionate and equitable deduction from the Primary Charge for the month in which said failure occurred, provided claim for such deduction be made within thirty (30) days after the end of the month in which the failure of delivery occurred.

Section 2. If in any month the Power Company shall be unable to deliver energy to the Railway Company, either in whole or in part, as required to be delivered by it under the provisions of this agreement, or the Railway Company shall be prevented from operating its regular train service, either in whole or in part, by strike, riot, insurrection, civil or military authority, fire explosion, act of God, railway accident, the complete or partial failure of the supply of energy from any other source, or by any other cause reasonably beyond its control, and if such inability and/or prevention shall cause the Railway Company's consumption of energy in such month to fall below the minimum amount specified in item (b) of Section 1 of Article VI hereof, then the number of kilowatt hours to be used in computing the Secondary Charge for such month shall not be less than the sum of

(a) the number of kilowatt hours which would equal..... per cent (.....%) of the total number of kilowatt hours which the power represented by the Billing Demand for such month could produce, if exerted during each and every hour of that month except the hours in which such inability and/or prevention occurred, and

(b) the number of kilowatt hours supplied during the hours in which such inability and/or prevention occurred.

Section 3. It is recognized that the Railway Company must receive from the Power Company a regular and uninterrupted supply of energy in accordance with the provisions of this agreement, in order to make this agreement of value to it; and if for any reason interruption of such supply of energy shall be so frequent or of such duration as to interfere materially with the operation of its lines of railway, or if the amount, quality or character of the energy delivered hereunder shall not be in accordance with the provisions of this agreement, then the Railway Company may notify the Power Company thereof in writing, specifying the grounds of complaint, and the Power Company shall forthwith remedy the trouble so specified and provide a full, regular and uninterrupted supply of energy in accordance with the provisions of this agreement. If the Power Company shall fail to do so with reasonable diligence and promptness and in any event within ninety (90) days from the date of such notice, the Railway Company shall have the right at its option to terminate this agreement by giving to the Power Company thirty (30) days' notice in writing of its intention so to do, stating in such notice the date of proposed termination, and this agreement shall terminate upon the date of termination

specified in said notice; provided, however, that if on any earlier date the Railway Company shall be able to obtain elsewhere the necessary energy required for the operation of its railway lines and shall give the Power Company notice in writing of such fact, this agreement shall terminate upon the date of such later notice.

Section 4. The Railway Company shall have the right at its option to terminate this agreement if the rates and charges herein specified shall be increased, pursuant to or by operation of law; also the Railway Company shall have the right at its option to terminate this agreement without assigning any cause therefor at the end of the .....year of the term or at the end of any twelve (12) months' period thereafter. In case of any termination as provided for in this section, the Railway Company shall give to the Power Company not less than eighteen (18) months' notice in writing of its intention so to do, and this agreement shall terminate upon the date of termination specified in such notice; provided, however, that upon such termination before the end of the original term, the Railway Company shall purchase from the Power Company such conversion and transmission apparatus and facilities as shall be then in use solely for the delivery of energy to the Railway Company under this agreement. The purchase price shall equal the actual cost less the sum of annuities of .....per cent (.....%) per annum of such actual cost from the time such apparatus and facilities shall first have been placed in operation for the sole benefit of the Railway Company to the date of termination. The actual cost of apparatus and facilities installed at the commencement of the term hereof for the sole purpose of delivering energy hereunder is hereby agreed to be.....Dollars (\$.....) (Description of apparatus and facilities and the cost thereof to be appended if so desired.)

Section 5. If the Railway Company fails to pay any bill of the Power Company as provided for in Article VI within ninety (90) days after such bill is due, the Power Company shall have the right to terminate this agreement by giving to the Railway Company not less than thirty (30) days' notice in writing of its intention so to do, stating in such notice the date of proposed termination, and this agreement shall terminate upon the date of termination specified in said notice.

Section 6. If the type of the equipment or if the operation of the equipment used by the Railway Company in connection with the energy taken hereunder interferes materially with the operation of the Power Company's system and service to its other customers, then the Power Company may notify the Railway Company in writing specifying the grounds of complaint and the Railway Company shall forthwith remedy the trouble so specified. If the Railway Company shall fail to do so with reasonable diligence and promptness and in any event within ninety (90) days from date of such notice, the Power Company shall have the right to terminate this agreement by giving to the Railway Company not less than thirty (30) days' notice in writing of its intention so to do, stating in such notice the date of proposed termination, and this agreement shall terminate upon the date of termination specified in said notice.

## ARTICLE IX

### REDUCTION IN RATES

If at any time during the term of this agreement, the Power Company shall deliver energy to any other consumer for service under similar conditions at a total rate or charge which shall be lower than that hereinbefore given to the Railway Company, and such lower rate or charge shall not be justified by different conditions of service, making the cost of production and delivery to such other consumer relatively less than to the

Railway Company (and the burden of proving such different conditions of service justifying the lower rate or charge shall be upon the Power Company), then and in that event and so long as such lower rate or charge shall be given to such other consumer while this agreement is in force, the Railway Company shall be entitled to a reduction in its said rate or charge equal to so much of the amount of the difference between such lower rate or charge and the Railway Company's said rate or charge as shall not be so justified.

If at any time during the terms of this agreement, the Power Company shall make a change in their method of generating, purchasing or transmitting electrical energy and if this change in the method of generating, purchasing or transmitting electrical energy shall result in a reduction in the cost per unit of electrical energy to the Power Company in excess of ten per cent (10%), the Railway Company shall be entitled to a corresponding reduction in the charges made for electrical energy purchased in accordance with this agreement.

#### ARTICLE X

#### ARBITRATION

In case any question arises under this agreement or concerning the subject-matter thereof, upon which the parties hereto cannot agree, such question shall be settled by a sole disinterested arbitrator, to be selected jointly by the parties to this agreement, and if they fail to select such arbitrator within..... (.....) days after demand for arbitration is made by either party hereto, then such arbitrator shall be appointed by the Judge of the.....Court of.....

The expense of arbitration shall be apportioned between the parties hereto, or wholly borne by either party, as may be determined by the arbitrator.

#### ARTICLE XI

#### GENERAL

Section 1. The Power Company shall have right of access to the premises of the Railway Company at all reasonable times during the period of this agreement, and on its termination, for the purpose of reading meters, inspecting or repairing appliances used in connection with its service, removing its property, or for any other purpose proper under this agreement.

The Railway Company shall not permit access, except by authorized employees of the Power Company, to the meters or other appliances of the Power Company, nor interfere with the same, and their safekeeping shall be provided for by the Railway Company.

Section 2. Whenever either party shall install any conduit, cable, wire or other apparatus or equipment in or upon the premises of the other party under any provision hereof, the party owning the same shall have the right, upon giving due notice to the other party, to repair or remove such apparatus or equipment at any and all reasonable times; provided, such repair or removal shall not interfere with the carrying out of this agreement; and upon the termination of this agreement by lapse of time or otherwise, such party shall at its own cost and expense, remove promptly and permanently any and all property owned by it upon the premises of the other party. Upon the removal of any property by either party from the premises of the other party as aforesaid, the party removing the same shall at its own cost and expense restore said premises to the same or as good condition as existed prior to the placing of said property thereon.

Section 3. The Railway Company agrees to indemnify and save harmless the Power Company from all cost, expense or liability for damages, which may arise or result from the use, care or handling of the energy delivered hereunder after the same shall have been delivered to the Railway Company at the points of delivery specified in Article V hereof, or from the presence upon the premises of the Railway Company of any appliances of the Power Company, except that the Power Company shall be responsible for all claims of its own employees, agents or servants.

The Power Company agrees to indemnify and save harmless the Railway Company from all cost, expense or liability for damages which may arise or result from the use, care or handling of the energy delivered hereunder before the same shall have been delivered to the Railway Company at the points of delivery specified in Article V hereof, or from the presence upon the premises of the Power Company of any appliances of the Railway Company, except that the Railway Company shall be responsible for all claims of its own employees, agents or servants.

Section 4. Any waiver or any number of successive waivers of any of the rights that may accrue to either party hereto through the default of the other party in keeping and performing any of the terms or obligations of this agreement shall not estop the party so waiving the default from asserting and having the benefit of its rights in accordance with the terms of this agreement upon any other or subsequent default, but at any time during the life of this agreement either party shall have the rights and benefits herein provided in case of default by the other party, without regard to any prior waivers or the number or time of such prior waivers.

Section 5. This agreement shall inure to the benefit of and be binding upon the legal representatives and successors of the parties respectively; provided, however, that this agreement shall not be assigned by the Power Company unless such assignment shall be made to another company having equal facilities to effectually perform, and which shall covenant to perform, the obligations herein of the Power Company.

IN WITNESS WHEREOF, the parties hereto have executed this agreement in.....  
.....the day and year first above written.

### Appendix C

#### (3) FORM OF CONVEYANCE OF TITLE GRANTING THE RIGHT TO CONSTRUCT AND MAINTAIN BUILDINGS OVER RAILWAY PROPERTY

R. P. Eubank, Chairman, Sub-Committee; W. D. Faucette, O. K. Morgan, H. A. Palmer, Huntington Smith.

Your Committee reports progress with Form of Conveyance of Title Granting the Right to Construct and Maintain Buildings over Railway Property.

#### Action Recommended

That this be accepted as a progress report and printed in the Proceedings as information and the basis for criticism and suggestions, and the subject be continued.

THIS INDENTURE, made this ..... day of ....., 19...., by and between ....., a corporation organized and existing under the laws of the State of ....., Grantor, and ....., a corporation, organized and existing under the laws of the State of ....., Grantee,

WITNESSETH: That for and in consideration of the sum of ..... Dollars (\$.....), and other valuable considerations, the receipt of which is hereby acknowledged, the Grantor conveys with ..... Warranty unto the Grantee, the following described land, property and space situate in the City of ....., County of ....., State of ....., to-wit:

(a) All the land, property and space at and above a horizontal plane ..... feet above ..... datum within and bounded by surfaces formed by projecting vertically upward from the surface of the earth the boundaries of the land bounded and described as follows: Beginning at the ..... (Insert description) ..... to the point of beginning, and containing ..... square feet, more or less, being a part of Lot No. ...., Block ....., of ..... Sub-Division of the City of ....., and as shown on map hereto attached, designated as ....., dated ....., of the ..... Engineer's office, and made a part hereof.

(b) Certain rights of support for structure as hereinafter set forth.

The Grantor's premises as aforesaid, below ..... elevation, not herein conveyed, are hereinafter referred to as the "ground space" and the term "..... datum" wherever used in this conveyance means the datum as now established by .....

The said ground space may be occupied and used by the Grantor for the construction, maintenance, use, operation and renewal of its railway tracks and facilities as they now exist or may hereafter be constructed for the operation and use of engines, trains, cars and other equipment and for all other purposes incident thereto; also for such other and different purposes as the Grantor, its successors or assigns, may from time to time or at any time hereafter deem advisable; and the Grantor, its successors or assigns, reserves the right, at its option, to lease, encumber or sell the ground space, subject to the

rights hereinafter granted to the Grantee, and also hereby covenants and agrees that such occupation and use by it of said ground space shall at all times be exercised in such manner as not to interfere with the rights in and to such ground space which are hereinafter granted in this conveyance to the Grantee.

The Grantor hereby further gives and grants to the Grantee, and to its successors or assigns, the perpetual right to construct, install, maintain and renew within the ground space, foundations, columns and bracing for the support of any buildings or other structures to be erected by the Grantee, all to be located and constructed in conformity with plans hereto attached and made a part of this conveyance and identified by the signatures of the Chief Engineer for the Grantor and the Architect for the Grantee, and to be designed, constructed, maintained and installed so as not in any manner to interfere with the Grantor's construction, maintenance and operation of its present tracks and facilities or tracks and facilities that may hereafter be constructed. The said right granted as aforesaid to the Grantee shall be and constitute an easement in and over said ground space perpetually running with the lands and premises hereby conveyed.

(Here insert any further grant or grants of easements in the ground space for sewers, pipes, tunnels, subways, etc., necessary or peculiar to the particular situation.)

The Grantor hereby reserves to itself, and to its successors and assigns, the right, without compensation to the Grantee, to attach wires, ducts, pipes, conduits and other apparatus and equipment and their supports to the columns, pedestals, inside of walls or underside of any buildings or other structures which may be erected by the Grantee, in, over or upon the ground space, and to repair, maintain and renew or to change the location of said wires, ducts, pipes, conduits and other apparatus and equipment and their supports.

And the parties hereto, in consideration of the premises, and of the mutual covenants herein contained, do further covenant and agree as follows:

(1) The Grantor covenants and agrees that it will, at the Grantee's sole expense, make such changes in the location of its tracks and structures within the ground space as shall conform to the locations thereof shown upon the plans attached hereto, and that it will, so far as may be reasonably practicable without undue interference of its service, co-operate in every reasonable way with the Grantee, to the end that the Grantee may promptly begin and prosecute to early completion the work of constructing its supporting foundations and columns.

(2) The Grantee covenants and agrees:

(a) That before erecting any buildings or other structures or foundations, columns or bracing therefor in, over or upon the ground space, it will submit detailed plans and specifications to the Chief Engineer of the Grantor, which shall conform in all respects as to size, location and dimensions within the ground space to the plans hereto attached, and shall provide a vertical clearance of not less than ..... feet above the top of the rails as they now exist; and the construction of such buildings or other structures or foundations, columns or bracing shall be subject to the approval and reasonable inspection, control and direction of said Chief Engineer.

(b) That in all its construction it will perform the work with the least possible interference with the property of and the operations of the Grantor and will, during said construction, provide, at its own expense, adequate and safe support for the Grantor's tracks and other facilities in strict accordance with the requirements of the Chief Engineer of the Grantor; the Grantor, however, reserving the right at any time to do all or

any part of the work necessary in connection with the proper support of its tracks and other facilities at the sole cost and expense of the Grantee.

(c) That any buildings or other structures erected in, over or upon the ground space shall be fireproof and shall be thoroughly waterproof and drained in the building drainage system, and that no water, liquid or waste of any character shall be permitted to drain or leak into the ground space.

(d) That it will make no alterations or changes in said buildings or other structures, which will increase the loads carried by the supporting foundations and columns in, over or upon the ground space without the written consent of the Grantor first had and obtained; that plans and specifications showing any such proposed alterations or changes shall be submitted to the Grantor for approval upon the application for such consent; and that all alterations or changes made with the written consent of the Grantor as aforesaid shall be made at the sole cost of the Grantee under the control, direction, inspection and approval of the Chief Engineer of the Grantor; also that proposed alterations and changes shall be first approved by the municipal or other governmental authorities having jurisdiction, and in accordance with such lawful orders and regulations as said authorities may from time to time make in regard thereto.

(e) That it will not permit the loading of any of the floors of any buildings or other structures at any time erected in, over or upon the land, property and space so conveyed, or any portion or portions of said floors, beyond the loads which the same will safely support, nor beyond the loads permitted by the municipal building code.

(f) That it will provide, construct, operate and maintain, at its own cost and expense, a system of ventilation for the purpose of exhausting smoke, other fumes and gases from locomotives or any cause whatsoever in the ground space, said system to include, among other features, openings over every track leading into smoke chambers which shall lead into a vertical stack or stacks in the buildings, so that the smoke, fumes and gases shall exhaust through the top of the buildings, the entire plan, arrangement and construction to be subject to the approval and satisfaction of the Grantor.

(g) That in the event of the use at any time, by the Grantor or other transportation companies using its station, of electricity or any other means of motive power for the running of locomotives, cars, trains or other facilities upon its tracks in the ground space, neither the Grantor nor said transportation companies shall be liable to the Grantee for any interference due to such use with telephone, telegraph, radio or other electrical apparatus or other instrumentalities of any kind or nature used by the Grantee or by others using or occupying said granted premises.

(h) That it will keep the buildings or structures sufficiently covered by fire insurance, and will not conduct or permit others to conduct in said buildings or structures any business in violation of any Federal, State or municipal law, and will keep the buildings or structures in such condition as the Board of Health or other lawfully constituted authority may require, free of all cost to the Grantor, and in accordance with the rules and regulations of the National Board of Fire Underwriters.

(i) That it will indemnify and save harmless the Grantor from and against any loss, damage, cost or expense by reason of the Grantee's failure in any respect to perform its covenants in this indenture entered into, or to comply with any obligation imposed upon it by law with respect to the land, property and space so conveyed, or by reason of any accident, loss or damage resulting to person or property in consequence of any act or omission by the Grantee in, over or upon the land, such as may arise or in any manner grow out of the construction, maintenance, presence, use or removal of any buildings or other structures placed over or upon the property and space so conveyed, and no approval by the Grantor of plans, buildings or other structures in, over or upon the land,

property and space so conveyed shall be construed to waive the foregoing covenants to save and keep the Grantor harmless and indemnified.

(j) That it will indemnify and save harmless the Grantor from all claims for property loss or damage, death or personal injury which may be suffered or sustained by the Grantee, its agents, servants, employees, invitees, licensees or tenants, on, over or upon the property herein conveyed, or in the buildings or structures located thereon, in connection with the exercise of the privileges herein granted, arising from any cause whatsoever.

(3) All general taxes levied and assessed against the ground space herein retained and the land, property and space herein conveyed,

(Here insert a provision for distribution of aforesaid taxes.)

The Grantee covenants and agrees to pay all taxes and assessments, general and special, of every kind and nature whatsoever levied upon any buildings or other structures at any time placed by the Grantee upon the land, property and space herein conveyed.

(4) All the covenants, conditions and undertakings herein shall inure to the benefit of and be binding upon the legal representatives, successors and assigns of the parties respectively, and shall be construed as covenants running with the land.

IN WITNESS WHEREOF, the parties hereto have executed this indenture the day and year first above written.

#### SUGGESTIONS FOR OTHER CONDITIONS THAT MAY APPLY AT CERTAIN LOCALITIES

1. The question of heating may come up and either company could put in a plant and serve heat to the other.

2. The question of maintaining approaches and streets would really be a part of the structure, but if there are any unusual approaches, there could be a clause added to take care of this.

3. Water supply and sprinkling system would develop in some localities and not in others. It might be well to consider which company should put in the system and allow the other to use same.

4. There would be quite a number of conditions that may come up at one locality that would not be essential at others. Therefore, it would not be advisable to put any more conditions in the contract than would generally be used at various locations.

5. The laws of different states vary as to the granting clause, testimony clause, signatures, witnesses, seals and acknowledgments; also tax laws. In all cases the indenture should be modified to meet the requirements of the State law.

6. In cases where there are contracts with the Western Union or other companies, there should be a clause added to protect the interests of those companies operating under contract from the Railway.

## Appendix D

## (4) FORM OF AGREEMENT FOR PIPE LINE CROSSINGS UNDER RAILWAY TRACKS

## (5) FORM OF AGREEMENT FOR USE OF RAILWAY PROPERTY BY PIPE LINES PARALLELING RAILWAY, WITH SPECIAL REFERENCE TO PIPE LINES CARRYING HIGH PRESSURE INFLAMMABLE OILS AND GAS

A. A. Miller, Chairman, Sub-Committee; B. S. Dickerson, F. H. Fechtig, J. P. Hanley, A. C. Jackson, J. A. Russell.

Your Committee recommends the following form for adoption and inclusion in the Manual:

THIS AGREEMENT, made this ..... day of ....., 19...., by and between ....., hereinafter called the Railway Company, and ....., hereinafter called the Licensee,

## WITNESSETH:

WHEREAS, the Licensee desires to construct, reconstruct, maintain and operate a ..... inch ..... pipe line for the handling of ....., under the tracks and/or upon the lands and property of the Railway Company, situated at or near ....., County of ....., State of ....., substantially as shown on Plan No. ...., dated ....., designated as ....., and the specifications hereto attached and made a part hereof,

It is mutually agreed as follows:

(1) The Railway Company grants permission to the Licensee to construct, reconstruct, maintain and operate said pipe line upon its lands and property and/or under its tracks in accordance with said plan and specifications hereto attached and forming a part hereof, subject to the conditions and requirements of this agreement.

(2) In consideration of this permit the Licensee shall pay to the Railway Company the sum of ..... Dollars (\$.....).

(3) The Licensee hereby acknowledges the title of the Railway Company in and to the premises described in this agreement and agrees never to assail nor resist said title.

(4) The Licensee agrees at its own cost, subject to the supervision and control of the Railway Company's Chief Engineer, or other designated officer, to lay and maintain the pipe line in such manner and of such material that it will not at any time be a source of danger to or interference with the safe operation of the railway. Arrangements must be made with the Chief Engineer or other designated representative of the Railway Company for the date and time for doing such work. Any work neglected by the Licensee or the contractor doing the work in connection with this laying or maintenance of the pipe line, or which the Railway Company would prefer to do itself, may be done by the Railway Company and the Licensee agrees to reimburse the Railway Company therefor.

(5) If any commission or other regulatory body duly constituted and appointed in compliance with Federal laws or the laws of the State in which the pipe line herein referred to is situated, shall by ruling or other general order prescribe a higher degree of protection than set forth herein or required under the attached specifications, then said ruling or general order shall be complied with for the pipe line referred to herein.

(6) The pipe, if used for conveying gas, natural or artificial oil, gasoline or other inflammable matter, matter under pressure or matter which from its nature may cause

damage, shall be laid and maintained when within ..... feet on each side of the nearest track inside an auxiliary or protecting pipe, and at a depth of not less than ..... feet below the base of rail where passing under the tracks, as set forth in the specifications. In the case of low pressure lines, modification of these requirements may be made with the approval of the Railway Company.

(7) If the Licensee desires or is required as herein provided to revise, renew, add to or alter in any manner the pipe line, or to increase its operating pressure or change the purpose for which the pipe line is used, it shall submit plans to the Railway Company and procure the approval thereof in writing before any work or increase of pressure or change of use in said pipe line is undertaken, and the terms and conditions of this Agreement shall apply thereto unless changed by mutual consent of the parties hereto.

(8) The Licensee agrees that in any future alteration of the alinement or grade of the Railway or the laying of additional tracks, the Licensee will bear the entire expense of changing said pipe line, to permit of said alterations of the alinement or grade of the railway, or the laying of additional tracks, so that the pipe line will continue to conform to the requirements of the Railway Company.

(9) The Licensee as part of the consideration for this permit hereby releases and waives any right to ask for or demand damages for or on account of loss or damage to the pipe line and contents thereof, whether attributable to the fault, failure or negligence of the Railway Company or otherwise.

(10) The Licensee shall indemnify, protect and save harmless the Railway Company from and against all claims, suits, costs, charges, causes of action, or damages made upon or incurred by the Railway Company in connection with this license.

(11) This permit is given and accepted upon the express condition that the same may be terminated at any time by either party by serving not less than ..... days' notice in writing upon the other party (stating therein the date when such termination shall become effective), and that, upon such termination the Licensee shall abandon the use of the pipe line laid in pursuance hereof and, if required by the Railway Company, remove the same and under the direction of the Railway Company restore the premises of the Railway Company occupied thereby to a condition substantially equal to the condition of said premises prior to the laying of said pipe line therein.

(12) In case the Licensee shall fail to remove its property or to restore the premises as aforesaid within ..... of said termination, the Railway Company may proceed with such work at the expense of the Licensee.

(13) No termination of this agreement shall release the Licensee from any liability or obligation which may have attached or accrued prior to ..... such termination, or under the provisions hereof relating to the duties of the Licensee after the service of notice of termination as herein provided.

(14) This agreement shall inure to the benefit of and be binding upon the legal representatives and successors of the parties hereto, but no assignment hereof by the Licensee, its legal representatives and successors, shall be binding upon the Railway Company without the written consent of the Railway Company in each instance.

IN WITNESS WHEREOF, the parties hereto have executed this agreement in ..... the day and year first above written.

## Appendix E

(6) FORM OF AGREEMENT WITH PUBLIC AUTHORITIES FOR  
HIGHWAY GRADE CROSSING ELIMINATION OR SEPARATION

J. S. Lillie, Chairman, Sub-Committee; E. H. Barnhart, B. Herman, C. B. Niehaus, Charles Silliman, W. R. Swatosh.

This subject has been in Committee two years. Last year we collected existing agreements from a number of railroads, covering elimination or separation of grade crossings in different states and Canada. These were carefully studied and a form prepared which has been revised some four or five times. Committee IX—Grade Crossings, has furnished suggestions with regard to this form of agreement.

It is recommended that this form of agreement be accepted and printed in the Proceedings as information and for discussion, and that the subject be continued.

FORM OF AGREEMENT WITH PUBLIC AUTHORITIES FOR HIGHWAY  
GRADE CROSSING ELIMINATION OR SEPARATION

THIS AGREEMENT, made this ..... day of ..... 19...., by and between the ..... Company, a corporation organized and existing under the laws of the State of ....., hereinafter called the "Railway Company", and the ....., acting through its ....., hereinafter called the .....

## WITNESSETH:

WHEREAS, it is desired to eliminate the grade crossing known and designated as ....., a public highway in the County of ....., State of ....., crossing the ..... tracks of the Railway Company at grade in the ..... of ....., County of ..... and State of ....., a distance of ..... feet ..... of the Railway Company's Mile Post ..... from .....; by separating the grades and a plan marked Exhibit A, a profile marked Exhibit B and specifications marked Exhibit C have been prepared, approved and accepted by both parties hereto as the manner of doing the proposed work, each sheet of the exhibits being identified by the signatures of the approving officers.

NOW, THEREFORE, in consideration of the covenants and agreements herein contained, it is mutually agreed as follows:

1. The grades of the public highway and the tracks of the Railway Company shall be separated and the ..... shall be carried over the ..... on a structure in accordance with the plan marked Exhibit A, profile marked Exhibit B, and the specifications marked Exhibit C, attached hereto, hereby approved and made a part of this agreement. Detail plans, including methods of performing the work and specifications for the materials to be used, amplifying Exhibits A, B and C, shall be prepared by the ..... and approved by the ..... before letting of any contract, purchase of any material or the performance of any work. Failure of the ..... to approve or notify the ..... of its objections to plans and/or specifications within ..... days after receipt will constitute approval by the .....

2. Subject to requirements deemed by it necessary for the safety of its traffic and the protection of its property, the Railway Company grants to the ..... the right to enter upon the following described premises and right-of-way of the Railway Company, ..... for the purpose of constructing, maintaining and/or reconstructing the structure shown on Exhibit A.

3. The Railway Company shall furnish all material, supplies and equipment for and by contract or with its own forces or a combination of both do and perform all the work of construction of the ..... and all other work appurtenant thereto or in connection therewith. (Division of work to be specified for each grade separation project) The ..... shall by its contractor or contractors, with its own forces or a combination of both, do and perform all other work of construction of the ..... and all work appurtenant thereto or in connection therewith, except as herein otherwise provided. All work shall conform to and comply with the terms of this agreement and the exhibits attached hereto.

4. The Railway Company shall, if it so elects, do any part or all of the construction work or changes of any character, affecting its tracks, including temporary structures under its tracks, detour tracks to facilitate construction, roadbed or the drainage of its right of way and/or lands necessary under this agreement. The Railway Company shall make all changes in its signals, telephone and telegraph lines and other similar facilities and/or change or cause to be changed telephone or telegraph lines of its licensees over which it has control, adjacent to and made necessary by the work provided for in this agreement. It is understood and agreed that all construction work and changes provided for in this section, except where the Railway Company licensees are required to make the necessary changes at their expense, are part of the work necessary for grade separation under this agreement and shall be included in the total cost and apportionment thereof.

The Railway Company shall, when, and if necessary in its opinion, provide watchmen and/or flagmen, to protect its property and the movement of its trains during construction. The expense thereof shall be paid by the Railway Company and shall be included in the total cost of the grade separation and the apportionment thereof.

5. Each party hereto shall keep accurate records of the work performed by its own forces. The cost of all materials and supplies so far as practicable shall be the cost f.o.b. the site of the work, including revenue freight. Where materials and supplies are furnished from the stocks of the Railway Company there shall be added to the storehouse price to cover the cost of supervision, inspection, transportation and accounting, ..... per cent (.....%). To the cost of labor of the Railway Company's forces there shall be added ..... per cent (.....%) to cover supervision, accounting and use of small tools. To the cost of the Railway Company labor shall be added Employer's Liability and Public Liability insurance costs. Equipment shall be charged to the work at the customary established rental rates of the Railway Company. No percentages shall be added to any work let by contract, provided, that on any work let by contract, the item of workmen's compensation and public liability insurance shall be carried by the Contractor and included as a specific item of cost.

As each party hereto proceeds with the work it is required to do, it shall prepare monthly estimates of the cost and expense of such work and an adjustment shall be made between the parties each month; such bills shall be due and payable at the office of their respective Treasurers on or before the ..... day of the following month.

6. The factors included in the cost and the division thereof between the parties hereto shall be as follows: .....

7. It is agreed ..... will, in letting any contract or contracts, require that the contractor, or contractors, shall furnish and deliver to the ..... a good and sufficient surety bond in a company licensed to do business in ..... for the faithful performance of all his obligations under the contract or contracts let, and which bond shall also protect, indemnify and save harmless the Railway Company and the ..... from and against and insure the payment by the contractor of any and all loss or damage or injury which they, or either of them, may sustain through injury to or death of any person or persons, loss of or damage to property of any person, firm or private or municipal corporation; and to protect, indemnify and save harmless the Railway Company and the ..... or either of them, from and against any and all claims, demands, suits and causes of action, judgments, costs, attorneys fees, and other expenses growing out of or resulting from any act of omission or commission or from a breach of the obligations of the contractor, his agents, servants or employees, in or incident to the construction of the ..... and/or the work attendant thereupon, any maintenance or repairs in connection therewith, and/or failure to comply with any of the requirements or obligations of this agreement.

The penal sum of the bond, if there be but one contract and bond, or the total of the penal sums of all such bonds, if there be more than one contract and bond, shall be ..... Dollars (\$.....). Each bond shall be subject to the approval of both parties to this agreement. The ..... shall cause the contractors to submit the bond or bonds to the ..... for approval before the execution thereof and the ..... shall, within ..... (.....) days after receipt thereof, notify the ..... and the contractor of its approval or disapproval of the bond or bonds. If the ..... shall disapprove the execution of the bond or bonds, it shall specify its reasons therefor.

8. Before beginning the work of construction on the Railway Company's property the ..... shall notify the Chief Engineer of the Railway Company in writing, of the date at least ..... (.....) days in advance of the date on which it is desired to start any work.

9. No waste excavation shall be deposited on the property of the Railway Company except with and under the written instructions of its ..... first had and obtained.

10. In the performance of said work no construction material or equipment shall be stored or placed by the ..... or its contractor upon the Railway Company's property except under the written authority and supervision of the Railway Company's ..... and then so as to not interfere with the operation or maintenance of the Railway Company's trains, roadbed, and/or tracks.

11. A minimum vertical clearance of ..... feet (.....') ..... inches (.....") over the top of the rail and a horizontal clearance of ..... feet (.....') ..... inches (.....") measured from the center line of the nearest track shall be maintained at all times during the construction. The clearance of the permanent structure shall conform to that shown on Exhibit A and shall conform to all Municipal Ordinances and State Laws and rules of other governmental bodies.

12. The ..... and its contractor or contractors shall comply with the rules and regulations of the Railway Company or the instructions of its representative in relation to the proper manner of protecting the tracks and property of the Railway Company and the traffic moving on such tracks, as well as wires, signals and other property of the Railway Company, its tenants or licensees at and in the vicinity of the work during the period of construction.

13. All water pipes, services or other underground conduits belonging to or controlled by the parties hereto and affected by the improvement herein provided for shall be taken care of so that they will function properly at all times during the construction of the improvement and the cost of caring for and of relaying or changing such facilities shall be considered a part of the cost of the grade separation work and included in the total cost and apportionment thereof.

All municipal or private corporations or individuals owning or maintaining wires, poles, pipes, conduits or other equipment or appliances, structures, or sub-structures for furnishing water, gas, telephone, telegraph, or electric service, or for transportation or for any other purpose, in the highway or on the property now owned or to be owned by the State and any municipality thereof, within the limits herein provided for or affected by construction of the ..... under this agreement, shall be required by the ..... to the extent of the exercise of its lawful powers, to change, relocate, or remove as may be, at their cost and expense, in such manner and to such extent as may be necessary to permit the changes and work herein contemplated and to support and keep the same in repair and operation during the progress of such work, upon notice from the .....

If, during construction any detours or temporary roads are necessary, the ..... shall arrange therefor and the cost thereof shall be borne by the .....

14. The ..... shall construct and maintain at its expense, a good and sufficient fence or guard, approved by the Railway Company, along the shoulder of the embankments on each side of the bridge, extending from the foot of the embankment to and connecting with the structure. Such fence or guard shall be of sufficient strength to prevent vehicles running off the approaches onto the tracks or property of the Railway Company.

15. The ..... or their duly authorized representative shall at all times construct, reconstruct, operate and maintain without cost or expense to the Railway Company any and all lights, signs (including highway symbols), signals and protection devices, necessary for the operation of, or required by law or order of any public body or commission having jurisdiction of or in connection with, the ..... road, structure, connecting highways, or any part of them, except that any bridge warning signals necessary along the Railway Company's tracks shall be installed and maintained by the Railway Company at its cost and expense.

16. The Railway Company shall have the right, subject to the reasonable supervision of the ..... without any charge to the Railway Company, to attach to the structure after its completion, at any time and from time to time, and to operate and maintain at the expense of the Railway Company, signals, signal posts or supports, telegraph, telephone or other wires, pipes and conduits and devices of whatever kind, nature and description that may now or hereafter be convenient or necessary in the operation of the railway.

17. The Railway Company shall have the right, subject to the reasonable supervision of the ....., without any charge and at the expense of the

Railway Company, to construct and use at any time and from time to time, driveways or roadways connecting the property of the Railway Company with said structure or its approaches.

18. The structure shall be maintained in accordance with this agreement, the exhibits attached hereto and detail plans and specifications provided for herein and any alterations or changes in that part of the structure on or over the property of the Railway Company shall be subject to the prior approval of the Railway Company in writing and shall be made at the sole cost and expense of the .....

Upon completion of the structure and all other work provided for in this agreement, the ..... shall, at its own cost and expense, maintain and repair ..... (including drainage necessary in connection with the approaches to the structure and the highway in the vicinity of the same), and the Railway Company shall, at its own cost and expense, maintain and repair ..... Provided that plans and specifications for all changes in maintenance or repairs made by either party or its contractors shall be submitted to the other party for approval and the party to whom such plans and specifications are submitted shall notify the other party within ..... (.....) days after receipt of such plans and specifications of its approval or disapproval. All maintenance of and repairs to the structure shall be so conducted as not to interfere with the operation of the Railway Company's tracks, trains, and/or property or that of its tenants.

19. In the event either of the parties hereto shall find it necessary after construction that the structure be altered, the work thereof shall be done as hereinabove provided for the original construction, each party to bear that part of the cost of such work as is done at its request and for its benefit except that where any changes are made, including strengthening for the purpose of carrying added loading, due to bus, truck and/or street car traffic, the Railway Company shall not be required to pay any part of such cost.

20. Rates being equal or better, the ..... shall give or cause to be given preference to the Railway Company's lines in the routing of all materials and supplies required in connection with the construction of the ..... To this end the Railway Company shall have the opportunity of approving the routing of all materials and supplies before shipment is started.

21. The structure and approaches thereto shall hereafter be held and considered as a public highway of the state and shall not be subject to taxation. The Railway Company shall not be liable for any special assessment levied against its property for or on account of said grade separation, its maintenance or repairs, nor on account of any highway widening or other improvement on or along said road known as ..... road.

For the purposes of this agreement it is hereby agreed by and between the parties hereto that the Railway Company is the owner of that part of the grade separation described as follows: ..... and that the ..... is the owner of all other parts of the entire grade separation project.

22. The ..... agrees to close or have closed to all traffic of every character, and permanently abandon, or have permanently abandoned as a public highway, the present road or highway crossings now in use and located at ..... and ..... The ..... also agrees not to open or permit to be opened, insofar as it can legally prevent the same, any public road or highway of any character across the tracks or right of way of the Railway Company within a distance of ..... of the structure

provided for in this agreement, without the consent of the Railway Company first had and obtained.

23. This agreement shall inure to the benefit of and be binding upon the parties hereto, their successors and assigns.

IN WITNESS WHEREOF, the parties hereto have caused this agreement to be signed ..... by their duly authorized officers, duly attested and their respective corporate seals to be hereunto affixed, the day and year first above written.

## REPORT OF COMMITTEE X—SIGNALS AND INTERLOCKING

P. M. GAULT, *Chairman*;

F. H. BAGLEY,

G. H. DRYDEN,

W. J. ECK,

W. H. ELLIOTT,

J. V. HANNA,

C. R. HODGDON,

C. A. MITCHELL,

J. C. MOCK,

R. D. MOORE,

H. G. MORGAN,

H. H. ORR,

J. A. PEABODY,

F. W. PFLEGING,

W. M. POST,

A. H. RUDD,

C. H. TILLET, *Vice-Chairman*;

LEROY WYANT,

T. S. STEVENS,

E. G. STRADLING,

C. A. TAYLOR,

W. M. VANDERSLUIS,

F. B. WIEGAND,

LEROY WYANT,

*Committee.*

*To the American Railway Engineering Association:*

Your Committee respectfully presents herewith report covering the following subjects:

2. Report developments of automatic train control, collaborating with Train Control Committee, A.R.A. (Appendix A).

3. Developments of automatic highway crossing protection, collaborating with Committee IX—Grade Crossings. A designated member of your Committee has collaborated as requested.

4. Increased efficiency secured in operation by signal indication, including remote control of switches, and centralized traffic control, in lieu of train orders and timetable superiorities, collaborating with Committee XXI—Economics of Railway Operation (Appendix B).

5. Synopsis of the principal current activities of the Signal Section, A.R.A., supplemented with list and references by number of adopted specifications, design and principles of Railway Operation (Appendix C).

6. Furnish the Special Committee on Clearances the information required by it pertaining to signals and interlocking. A designated member of your Committee has collaborated as requested.

### Action Recommended

2. That Appendix A be received as information.
4. That Appendix B be received as information.
5. That Appendix C be received as information.

Respectfully submitted,

THE COMMITTEE ON SIGNALS AND INTERLOCKING,

P. M. GAULT, *Chairman*.

### Appendix A

#### (2) DEVELOPMENTS OF AUTOMATIC TRAIN CONTROL

W. J. Eck, Chairman, Sub-Committee; W. H. Elliott, F. W. Pfleging.

#### AUTOMATIC TRAIN CONTROL

Since the last report, as printed in the Advance Notice for the May, 1933, meeting, the following roads have filed petitions with the Interstate Commerce Commission for modification of the train control orders, with the following results as of October 18, 1933:

To discontinue operation of automatic train control:

|                                             |         |
|---------------------------------------------|---------|
| Chicago, Indianapolis & Louisville.....     | Granted |
| St. Louis-San Francisco .....               | "       |
| Boston & Maine.....                         | Denied  |
| Chicago, Milwaukee, St. Paul & Pacific..... | "       |
| Baltimore & Ohio .....                      | "       |
| Norfolk & Western .....                     | "       |
| Alton .....                                 | Pending |
| Southern Pacific .....                      | "       |

To discontinue operation of automatic train control and operate by cab signals in conjunction with wayside signals:

|                                      |         |
|--------------------------------------|---------|
| Norfolk & Western .....              | Granted |
| Delaware, Lackawanna & Western ..... | "       |
| Pennsylvania .....                   | "       |
| Reading .....                        | "       |
| Central Railroad of New Jersey ..... | "       |
| Long Island .....                    | "       |
| Boston & Maine .....                 | Pending |

The three decisions now pending involve the following conditions:

Southern Pacific to discontinue operation of nearly three-fourths of its mileage; Alton to discontinue operation of its entire installation; and Boston & Maine to dispense with the brake applying apparatus and operate by cab signal indicator and wayside signals.

In all cases where petitions were granted approval was given "until further order of the Commission"; also the installations changing to cab signals were subject to inspection and approval.

The operation of a total of 1738 track miles of automatic train control, not including the Alton and Southern Pacific, has been discontinued by Interstate Commerce Commission authority, involving a reduction of 640 locomotives and 10 motor cars from the total equipped. Installations changed from train control to cab signals total 3155 track miles, not including the Boston & Maine, involving 1876 locomotives and 295 motor cars of the total originally equipped with automatic train control.

The Committee on Automatic Train Control has continued its studies on interchangeability but has, due to general economic conditions and on account of the fact that certain types of devices are being eliminated from present consideration, refrained from initiating further field tests and experiments along these lines. It still considers that the subject is worthy of consideration and the attention of the members is called to the remarks of S. N. Mills, Assistant Director of the Bureau of Safety, Interstate Commerce Commission, before the last annual meeting where he stated "that interchangeable operation should be provided for wherever practicable in changing over from train control to cab signal operation and should certainly be provided for in any future installations of automatic cab signal devices".

The Committee on Automatic Train Control has prepared and approved a set (Exhibit A) of proposed standard aspects and indications for continuous automatic cab signals. These proposed standards are in accord with the A.R.A. Standard Code, and are to be presented to other interested sections and divisions of the American Railway Association for approval as standard practice. This work was undertaken at the suggestion of the Bureau of Safety. On Exhibit B are shown the specifications and requirements for continuous automatic cab signal system as prescribed by the Interstate

Commerce Commission in the case of the following railroads, all of which have way-side signals:

Norfolk & Western  
Delaware, Lackawanna & Western  
Pennsylvania  
Reading  
Central Railroad of New Jersey  
Long Island

The Committee on Automatic Train Control and the Bureau of Safety are continuing to co-operate in investigations that appear desirable, in order that information may be secured with respect to irregular functioning of apparatus. A recent investigation of the effect of continuous receivers coming in contact with safety hangers or chains, or being loose on supports, and the effect on proper operation, has been completed. These experiments involved both laboratory roadway, and roundhouse work, and interesting data and conclusions were reached.

## Appendix B

### (4) INCREASED EFFICIENCY SECURED IN OPERATION BY SIGNAL INDICATION, INCLUDING REMOTE CONTROL OF SWITCHES, AND CENTRALIZED TRAFFIC CONTROL, IN LIEU OF TRAIN ORDERS AND TIMETABLE SUPERIORITIES

W. M. Post, Chairman; W. J. Eck, P. M. Gault, W. M. Vandersluis, G. H. Dryden, C. A. Mitchell.

Committee X has presented several reports showing the savings and increased efficiency secured in railway operation by signal indications in lieu of train orders and timetable superiorities. The Committee presented reports in 1932 and 1933 on the economic results of centralized traffic control installations. In addition to definite money savings due to block and interlocking stations discontinued, and gross ton miles per train hour increased, there is an increase in the margin of safe operation, which results in intangible savings which cannot be definitely determined, but which are nevertheless real.

This report relates to intangible benefits and savings difficult to determine accurately provided by a Centralized Traffic Control installation.

### A CENTRALIZED TRAFFIC CONTROL SYSTEM

1. Reduces number of written train orders. Prior to installation of Centralized Traffic Control on the New York Central Lines between Berwick and Stanley (40 miles of single, 3 miles of double track), an average of 90—"31" orders and 3600—"19" orders per month were issued. Since the Centralized Traffic Control installation in 1927, no written train orders have been issued for execution in the Centralized Traffic Control section. Orders are conveyed by signal indication at the time and place they are to be executed. Special instructions are transmitted to trainmen by telephone.

2. Reduces errors in the transmission of orders. Orders are transmitted by signals, which are surrounded by mechanical and electrical safeguards. If the control operator displays a signal not intended, protection against conflicting movements is automatically provided.

3. Eliminates possibility of errors in interpretation or execution of written orders.

4. Eliminates delays due to waiting for written train orders.
5. Provides complete information constantly available concerning train movements. Lights on the machine indicate position of switches and signals and occupancy of track at passing siding switches, and, in many cases, in blocks between passing sidings. Train graph provides a record of time of trains between passing points.
6. Provides means so that disregard of stop signal indication can be instantly detected by the control operator. The knowledge that the control operator can by observing the lights on the machine detect any disregard of a Stop signal tends to keep the engineman alert and thus reduces the chance that signals will be passed when displaying Stop.
7. Saves stops or reduction in speed for delivery of train orders.
8. Provides facilities for non-stop meets at passing sidings.
9. Eliminates stops due to necessity for train crews to operate hand-thrown switches.
10. Decreases damage to equipment and lading caused by stopping and starting trains.
11. Decreases personal injuries caused by stopping and starting trains.
12. Provides immediate information as to whether or not trains are losing time, and control operator is better able to plan the meets at passing sidings.
13. Facilitates meets on close schedule and reduces time for clearing main line for superior trains.
14. Provides means for checking speed of trains between stations and delay at stations.
15. Provides facilities for handling peak traffic conditions with no loss of efficiency.
16. Provides greater protection for the movement of motor cars and other equipment of the Maintenance of Way Department and control operator can protect their movements by signals when conditions require.
17. Eliminates possibility of throwing switches immediately ahead of an approaching train, as switches are equipped with approach locking.
18. Provides signals for train movements entering and leaving sidings.
19. Provides facilities for stopping, holding or re-routing trains, which control operator may use when necessary.
20. Tends to reduce the number of locomotives required and per diem charges.
21. Increases good-will on account of decreased time of goods in transit.
22. Increases average speed in miles per hour over the territory.

### Appendix C

#### (5) SYNOPSIS OF THE PRINCIPAL CURRENT ACTIVITIES OF THE SIGNAL SECTION, A. R. A., SUPPLEMENTED WITH LIST AND REFERENCES BY NUMBER OF ADOPTED SPECIFICATIONS, DESIGNS AND PRINCIPLES OF SIGNALING PRACTICE

E. G. Stradling, Chairman, Sub-Committee; H. H. Orr, Leroy Wyant.

#### CURRENT ACTIVITIES OF THE SIGNAL SECTION A.R.A.

Since March, 1933  
(As of November, 1933)

1. Revised Regulations for Membership in the Signal Section of the A.R.A.
2. Continued the work of standardization of colored glasses, receiving the co-

operation and help of the Corning Glass Works and the Bureau of Standards, Colorimetry Section, at Washington.

3. Continued the study of reflecting devices as a substitute for oil or electric lights.
4. Making a study of the shunting of A C track circuits by rubber tired oil-electric passenger cars.
5. Kept in touch with those roads using automatic train control. Compiling information as to present day practices.
6. Decided upon a conclusion on Economical Train Performance on Single Track.
7. Prepared new requisite for Signal Protection for Spring Switches.
8. Prepared and recommended a Design for Spring Switch Marker.
9. Prepared and recommended a Design for Grade Signal Marker.
10. Adopted A.R.E.A. forms for Construction Contract, Proposal and Bond.
11. Prepared an Example showing Use of Unit Value Basis in connection with interlocking plants.
12. Revised Forms for Wire Inspection Report.
13. Prepared instructions for Maintenance and Operation of Direct Current Track Circuits.
14. Prepared definitions for technical terms:
  - Chromatic Aberration.
  - Centralized Traffic Control.
  - Dual Control.
  - Drawbridge.
  - Reflector Unit.
  - Double Refraction Reflector.
  - Single Refraction Reflector.

# SPECIFICATIONS REVISED

## Specifications and Requirements for Continuous Automatic Cab-Signal System

## DEFINITIONS

For purposes of these specifications, the following definitions will apply:

**AUTOMATIC CAB-SIGNAL SYSTEM.**—A system which provides for the automatic operation of the following:

- (a) Cab signal—a device located in the cab which, when locomotive and roadway apparatus are in operative relation, displays indications of conditions in advance.
- (b) Cab indicator—a device located in the cab which indicates a condition or a change of condition of one or more elements of the system.

**BLOCK.**—A length of track of defined limits, the use of which by trains is governed by fixed signals or cab signals or both.

**CABS.**—The compartment occupied by engineman, fireman or motorman, of the engine, motor car or multiple-unit car from which the propelling power of the train is controlled.

**CONTINUOUS CONTROL.**—A type of control in which the locomotive apparatus is constantly in operative relation with the track elements and is immediately responsible to a change of conditions in the controlling section which affect train movement.

**CONTROLLING SECTION.**—A length of track of one or more track circuit sections by which the track elements governing approach to, or movement within, a block are controlled.

**LOCOMOTIVE.**—A self-propelled unit of equipment used in train service.

**TRACK ELEMENT.**—That portion of the roadway apparatus to which the locomotive apparatus is directly responsive.

## SPECIFICATIONS

1. The purpose of these specifications is to prescribe essential features involved in the design, construction, installation, operation and maintenance of automatic cab-signal systems of the continuously controlled type, without automatic train control.

2. The automatic cab-signal system shall function to display a cab-signal indication which constantly corresponds with conditions in advance in the controlling section.

3. The automatic cab-signal system shall be so arranged that a change of conditions affecting train movement which occurs within braking distance in advance will result immediately, regardless of the location of the locomotive in the controlling section, in a change of cab-signal indication corresponding with these changed conditions.

4. The automatic cab-signal system shall be so arranged that when a locomotive enters and is within a block in which there exists a condition causing a restrictive indication the cab signal will display the most restrictive indication required by that condition.

5. The automatic cab-signal system shall be so arranged that when the cab signal changes to display a more restrictive indication an audible cab indicator will sound and continue to sound until acknowledged.

6. The automatic cab-signal system shall be so interconnected with the fixed-signal system that the cab signal will display indications consistent with the indications of the fixed signals, except when a fixed signal displays a less restrictive indication than is required or warranted by existing conditions.

7. The cab signals shall be plainly visible to members of the locomotive crew when they are in their accustomed stations in the cab.

8. The cab indicator shall have a distinctive sound which will be clearly audible to members of the locomotive crew under all operating conditions when they are in their accustomed stations in the cab.

9. The automatic cab-signal system shall be so constructed that the cab signal will, so far as practicable, display its most restrictive indication if an essential part fails or is removed, or a break, cross or ground occurs in electric circuits, or in case of a failure of energy.

10. The apparatus shall be so constructed that proper operative relation between the parts along the roadway and the parts on the locomotive will be assured under all conditions of speed, weather, wear, oscillation and shock.

11. The apparatus shall be so constructed as not to interfere with the application of the brakes by operation of the engineman's brake valve or to impair the efficiency of the air-brake system.

12. The apparatus shall be so constructed that it may be applied so as to be operative when the locomotive is running forward or backward.

13. The apparatus shall be so constructed that it will operate under all weather conditions which permit train movements.

14. The apparatus shall be so constructed as to conform to established clearances for equipment and structures.

15. The apparatus shall be so constructed and installed that it will not constitute a source of danger to trainmen, other employees, or passengers.

16. The apparatus shall be so constructed, installed and maintained as to be safe and suitable for service. The quality of materials and workmanship shall conform to this requirement.

A

## REPORT OF COMMITTEE XVIII—ELECTRICITY

W. M. VANDERSLUIS,  
*Chairman;*  
H. M. BASSETT,  
D. J. BRUMLEY,  
H. A. CURRIE,  
J. H. DAVIS,  
J. S. HAGAN,

PAUL LEBENBAUM,  
W. L. MORSE,  
R. J. NEEDHAM,  
E. H. OLSON,  
A. E. OWEN,  
J. A. PEABODY,

J. V. B. DUER, *Vice-*  
*Chairman;*  
H. W. PINKERTON,  
J. M. TRISSAL,  
R. P. WINTON,  
SIDNEY WITHINGTON,  
G. I. WRIGHT,  
*Committee.*

*To the American Railway Engineering Association:*

Your Committee has been instructed to (1) Keep the Association informed of developments in the application of electricity to railway service, and (2) present a synopsis of the current activities of the Electrical Section, supplemented with list and reference by number of adopted specifications, designs and principles of practice.

Reference is made to the series of reports made by committees of the Electrical Section, reprinted in full in Bulletin 359, for September, 1933.

No session of the Electrical Section was held in 1933, therefore no action has been taken on the reports submitted.

A condensed summary of these reports is given below.

### SUMMARY OF REPORTS

#### 1. Developments in Application of Electricity to Railway Service

A useful bibliography of articles appearing in a selected list of periodicals covering period January, 1932 to June, 1933, forms basis of report.

#### 2. Inductive Co-ordination

Report is made on the issuance of a set of "Principles and Practices for the Inductive Co-ordination of Railway Electrical Supply Facilities and the Communication Facilities of the Bell Telephone System." Cooperative work with the Edison Electric Institute on "Principles and Practices for the Inductive Co-ordination of the Wire Systems of Railways and Central Station Companies" is continuing and is partially completed. A statement is presented regarding co-ordination measures employed on the Chicago, Milwaukee, St. Paul & Pacific Railroad electrification. The report also contains a review of article appearing in the "Oerlikon Bulletins," regarding the impedance of the overhead line and return conductors of single-phase railways, and what influence the current return path has on it.

#### 3. Power Supply

Reference is made as to the general progress of electrical power supply in the United States, and to a limited extent in other parts of the world, to articles appearing in "Power" January, 1933, and to "Electrical World," May, 1933. In connection with railway electrification developments in the United States, the large Pennsylvania Railroad program is by far the most important. Reference is made to a description of this extensive project by J. V. B. Duer, on "Power Supply for the Pennsylvania Railroad," presented before the A. I. E. E., January, 1933. Railway electrification developments in Sweden and France are reported on. The position of electric power supply in the United

States for 1932 is summarized. Report is also made on servicing equipment along right-of-way for air-conditioning and pre-cooling of cars. The procedure followed and the equipment used on a number of roads is listed.

#### **4. Electrolysis**

Report is made on the elimination of the effects of electrolysis by the use of non-metallic sheathed cables. In view of the fact that considerable development may be expected within the next few years of the use of non-metallic sheathed cables for the mitigation of the effects of electrolysis, this study will be continued.

#### **5. Co-operation in Miscellaneous Regulations**

Progress is reported on this assignment.

#### **6. Overhead Transmission Line and Catenary Construction**

Progress report only. Consideration is being given to a proposal to modify existing specifications for bronze trolley wire so as to include a high conductivity wire under the auspices of a joint committee, composed of representatives of the Electrical Section, American Society for Testing Materials and American Transit Association.

#### **7. Standardization of Apparatus and Materials**

Progress is reported on revision of Specifications for Friction Tape, Rubber Insulating Tape, and for Porcelain Insulators. Recommendation is made that individual members review the list of ASA standards with the view of applying such approved specifications on their individual railroads, and the consequent savings accruing from such general use are pointed out.

#### **8. Electric Heating**

The report deals with (1) application of heat for various purposes; (a) electric snow melters; (b) water heaters and space heating; and (c) miscellaneous electric heating; (2) electric welding and equipment (as applied to maintenance of way work). As these subjects are relatively new to the Electrical Section, their development in railway work will be followed closely.

#### **9. Application of Motors**

The report deals with the application of different types of motors, both standard and special, for uses other than rolling stock. The report is divided into (a) alternating current motors; (b) direct current motors; (c) special equipment; (d) standardization, and (e) application of proper motors.

#### **10. Clearances for Third-Rail and Overhead Working Conductors**

A series of tables are presented indicating the present-day practices on electrified roads covering Third-Rail and Overhead Conductor Clearances and mileage in operation as of October 1, 1933. Progress is also reported on revision of the clearance lines for equipment and permanent way structures adjacent to third-rail and third-rail structures.

#### **11. Protection of Railroad Equipment from Danger of Fire Caused by Electric Sparks During the Transfer of Inflammable Liquids**

The report consists of a revision of the current rules for the protection of oil sidings, covering a change in the wording of the title for greater clarity; Section A amplified for reasons of clarity; Section C-1 added to simplify the protective measures and a saving

in the expense where there is no danger from stray earth currents; Section C-2 enlarged to provide against bridging of insulated rail joints; Section C-3 added to provide protection from flashes from trolley wires or third-rails; Section C-5 added as a precaution against high resistance; Section D omitted as unnecessary. Recommendation is made that the revised rules be submitted to the Mechanical and Motor Transport Divisions, the Association of Railway Electrical Engineers and the American Petroleum Institute for comment.

#### **12. Specifications for Track and Third-Rail Bonds**

Progress is reported on this assignment, with recommendation that it be continued.

#### **13. Illumination**

Minor changes in the lamp schedules are proposed. Report contains developments in incandescent lamps—(a) general purposes lighting; (b) new lamp and lighting developments for special purposes; (c) locomotive and train lighting lamps; (d) lamp tests and rejections. Report is also made on floodlighting in railroad yards.

#### **14. Design of Indoor and Outdoor Substations**

The report deals with (1) AC protection of substations (a continuation of last year's report); (2) insulation coordination; (3) high-speed trolley circuit breaker performance; (4) new apparatus developments.

#### **15. High Tension Cables**

Report cites the installation across the East River, New York, of 14 cables, and of an installation of 15 cables at Wallabout Bay, New York. Reference is also made of one installation of a large section single-conductor cable at 69 k.v., in which the copper section was made up of several lightly insulated sections in the effort to reduce skin effects.

#### **16. Application of Corrosion-Resisting Materials to Railroad Electrical Construction**

Progress is reported on the results of observations of samples installed at New Haven, Conn., and at Hemphill Tunnel on the Norfolk & Western, and also at Lambert's Point pier.

#### **17. Form of Power Contract for Large Blocks of Power**

Progress is reported on this assignment.

#### **18. Radio Antennae on Cars in Electrified Territory**

Progress is reported on this assignment.

### **Action Recommended**

That the report of the Committee on Electricity be accepted as information.

Respectfully submitted,

THE COMMITTEE ON ELECTRICITY,

W. M. VANDERSLUIS, *Chairman*.

## REPORT OF COMMITTEE I—ROADWAY

GEO. S. FANNING, *Chairman*; H. H. HARMAN,  
J. B. AKERS, F. W. HILLMAN,  
C. W. BALDRIDGE, C. T. JACKSON,  
E. J. BAYER, G. E. LADD,  
W. G. BROWN, W. J. LANK, JR.,  
G. H. BURNETTE, HAROLD W. LEGRO,  
PAUL CHIPMAN, E. R. LEWIS,  
A. A. CROSS, H. T. LIVINGSTON,  
L. J. DRUMELLER, J. A. NOBLE,  
G. B. FARLOW, ROSCOE OWEN,  
P. D. FITZPATRICK, R. H. PINKHAM,  
L. C. FROHMAN, W. C. PRUETT,  
J. A. GIVEN, C. S. ROBINSON,  
J. N. GRIM,

A. E. BOTTS, *Vice-Chairman*;  
L. S. ROSE,  
C. S. SAMPLE,  
P. T. SIMONS,  
E. M. SMITH,  
H. E. STANSBURY,  
W. C. SWARTOUT,  
H. M. SWOPE,  
J. B. TRENHOLM,  
O. H. WAINSCOTT,  
THOMAS WALKER,  
J. C. WALLACE,  
A. W. WHITE,  
F. E. WIESNER,

*Committee.*

*To the American Railway Engineering Association:*

Your Committee respectfully presents its report on the subjects assigned:

1. Revision of Manual. No revisions are recommended except those to be made in connection with subjects 2 and 6.

2. Methods of Roadbed Drainage (Appendix A). This report concludes the consideration of this subject in accordance with the outline adopted in 1931. It is recommended that the matter in Appendix A, beginning with "(c) Maintenance" and ending at "Recommendations" be adopted for inclusion in the Manual to follow the matter adopted last year and that the changes in the Manual as listed under "Recommendations" be made. The purposes of these changes are to bring the definitions and the "Specifications for the Formation of the Roadway" in harmony with the recommended practice adopted for roadbed drainage, to remove from the Manual present matter on slides, water pockets, soft spots and ditching, the substance of which has been included in the above report or is obsolete, and to replace the figure on page 41 illustrating drainage with more comprehensive plates.

3. Study the service life of and prepare specifications for railway fence wire. Progress reports on this subject have been offered for several years covering various tests being made on fence wire. The Committee is keeping in touch with these tests and hopes to draw conclusions therefrom which will warrant submitting a specification next year.

4. Practice of jacking culvert pipe through fills (Appendix B). In making this report, the Committee had in mind providing a source of information for those unfamiliar with work of this kind from which they could secure sufficient data to prepare an estimate of cost and to carry out the work. It is recommended that the report be received as information.

5. Bearing power and other physical properties of soils including effect upon roadbed (Appendix C). In this report the Committee indicates some respects in which soil engineering is undergoing change and includes a glossary of soil terms. It is recommended that the report be received as information.

6. Methods of protection against drifting snow and of opening snow blockades (Appendix D). This report is a reconciliation of the report submitted last year as information and the matter on Snow Fences, Snow Sheds and Recommended Methods of Snow Removal now contained in the Manual. It is recommended that the matter

in Appendix D under the headings "Protection against Drifting Snow" and "Opening Snow Blockades" be adopted for inclusion in the Manual replacing the present material referred to above.

7. Specifications for galvanizing metal culvert pipe. Progress is reported on this subject with a recommendation that the subject be broadened to include a complete review of the Specifications for Corrugated Metal Culvert Pipe with a view to developing an American Standard.

8. Service life of culverts. This is a new subject and an extensive one. The Committee reports progress in organizing its work.

9. Methods of protection against drifting sand (Appendix E). Letters on this subject have been received from all parts of the world. The more interesting have been quoted in the report, which is offered with the recommendation that it be received as information and that the conclusions be adopted for inclusion in the Manual.

Respectfully submitted,

THE COMMITTEE ON ROADWAY,  
GEO. S. FANNING, *Chairman*.

## Appendix A

### (2) ROADBED DRAINAGE

H. M. Swope, Chairman, Sub-Committee; G. B. Farlow, P. D. Fitzpatrick, H. H. Harman, G. E. Ladd, E. R. Lewis, C. S. Sample, P. T. Simons, E. M. Smith, T. Walker, A. W. White, F. E. Wiesner.

Consideration of this subject has been continued in accordance with the outline adopted in 1931 (Proceedings, Vol. 32, page 170). The subject-matter developed by this Committee has been adopted for publication in the Manual and is to be found in Proceedings, Vol. 32, pages 169 to 172; Vol. 33, pages 304 to 309; Vol. 34, pages 132 to 137. The following report concludes the study of this subject as outlined and is offered for publication in the Manual:

### (C) MAINTENANCE

#### (I) MAINTENANCE OF DITCHES

##### Causes

Ditch repairs may be necessary because of construction faults or deferred maintenance. If the gradient is unsuitable, the ditch may scour and cut, or accumulate silt.

Excessive grade tends to such rapid flow of water as to scour the bottom and undermine the slopes which slide in and form obstructions to flow, thus producing eddies and cross currents which aggravate the undesirable conditions.

Insufficient grade results in gradual silting. Unchecked growth of vegetation chokes the stream, obstructs water flow, and thus causes silt deposits.

Some soil wears away readily, the slopes are eroded by rainfall and undermined by the current of water in the ditch, unless the gradient is correct and the stream bed clear.

##### Maintenance

Alert and methodical inspection, with prompt remedy of large and small defects, is necessary to economical maintenance of ditches. The object is to preserve the original section as nearly as possible by preventing obstructions which tend to divert or

obstruct the flow. Repairs to drainage ditches should be made when conditions require, but a general program of repairing and cleaning should be conducted annually, preferably in the fall.

Erosion may take place at curves, especially during high water, and can be prevented by the placing of riprap, brush bundles, or concrete blankets.

Excessive grades may be counteracted with riffle dams of brush, stone, or other available material. While vegetation may be grown to prevent slope erosion, it should not be permitted to restrict the cross-section of the ditch, which should be kept free of all obstacles to free flow of water.

Obstructive snow and ice must be cleared from ditches for their preservation, to prevent wash, and to prevent the hazard of ice forming on the track during alternate thawing and freezing weather.

Intercepting and drainage ditches, other than side ditches in cuts, should be cleaned by hand work, teams and scrapers, power shovels or drag lines, depending upon the size of the ditch and kind and volume of material to be handled.

Ditching of ordinary material in side ditches in cuts may be subdivided into two principal classes:

1. Shallow Cuts
2. Deep Cuts

### 1. Shallow Cuts

On lines where ditching is done currently the work can usually be performed by hand or with spreaders equipped with wings for shaping ballast and roadbed shoulders, ditches and slopes. If maintenance has been deferred and the volume of material to be handled is large, teams with scrapers are economical in cuts sufficiently wide for safe operation.

### 2. Deep Cuts

On lines where ditching is done currently the work can usually be performed with spreaders. If the volume of material to be removed is small, hand labor, with motor cars, push cars and dump beds, wheelbarrows or trackbarrows should be considered.

In either of the above classes other means of ditching may be necessary when an accumulation of dirt from the spreading process fills the available space outside of the ditch. Deferred maintenance or the nature of the material involved may also make this necessary.

Where the volume of cleanings is large or the points of disposal remote, it will usually be more economical to use power ditchers.

Auxiliary track and small cars may be used economically on heavy traffic lines where there is sufficient clearance, provided the haul is long and the volume of material to be handled would justify the initial cost of the plant installation.

In all cases where the material is cast out it must be so placed to prevent it from washing back into the cut. Material removed from side ditches should never be cast upon the adjacent slope.

When waste dirt is disposed along embankments, it should be wasted at an elevation below the bottom of the ballast.

The use of work trains with hand labor is generally uneconomic, and is not recommended.

## Ditching Machines

There are a number of items and conditions which should be considered before undertaking work with ditching machines and their equipment—interest on investment, depreciation, upkeep, work train service and interruption to traffic are vital items which

should not be overlooked. Equipment of this class has advantages which should also be taken into consideration. Ditching machines have a wide scope of operation; they will move large volumes of material in a comparatively short time; they make it practicable to utilize the material excavated for bank widening, trestle filling, if material is suitable, or other like work.

The use of power ditchers and their equipment is recommended in work where the cuts are long and deep, or where the volume of material to be moved is large, or where the material is wet and difficult to handle by other methods. Their use is also recommended where cuts are resloped or widened to such a limited extent as not to justify the use of power shovel. Under similar conditions they may be used for widening embankments. They are particularly efficient in removing small slides or other like emergencies where material is wet or hard to handle.

The chief considerations relative to use of such equipment is density of traffic and the volume of work to be performed.

The shaping of the roadbed and ditch after ditching should be performed by a spreader, when the nature of the material and the width of the cut will permit. Otherwise this work must be done by hand.

## (II) MAINTENANCE OF DRAINS

### Pipe Drains

1. General: Drainage systems are expensive and valuable. After installation the drains must be given enough care and attention to obtain from them the maximum life and service. Record plans made at the time of construction should be carefully preserved for reference and any changes made promptly noted thereon.

2. Inspection: In addition to a yearly inspection, roadmasters, track foremen, and others responsible for their maintenance, should make periodic inspections to see that the drainage systems receive adequate maintenance.

3. Markers: Limits of covered drains should be marked with adequate signs to facilitate inspection and maintenance.

4. **Outlet ditch:** Ditches leading from outlet pipes should be kept clean, with adequate width, depth, and grade to insure proper drainage. Side banks should be maintained with sufficient slope that the material involved will not cave. Ditches should be maintained free of vegetation, debris and other obstructions. Irregularities in alignment and grade tend to cause silting and scouring and should be avoided.

5. **Outlet pipes:** Screens on outlet pipes should be kept in place to prevent small animals entering pipes. When silting occurs at outlet, screens should be removed and the outlet cleaned. Special care should be given outlets to make certain that stoppage does not occur.

6. **Overflow:** Occasionally outlet pipes discharging near bridges and culverts are subject to overflow or backwater during high water. Inspection should be made as soon as water recedes and if necessary the pipe drainage system should be flushed.

7. **Flushing:** Frequent inspection of the mains should be made through the risers. Any tendency to silt should be carefully watched and when it occurs to a marked degree, the entire system of mains should be flushed with hose from water car or other convenient supply. This is especially necessary for systems involving light grades.

8. **Vegetation:** Trees, bushes or vegetation with deep roots should not be allowed to grow near any line of sub-surface drain pipe. The roots, seeking water, may fill the pipes and cause stoppage of the system.

9. **Failure:** Rapid silting of main drains indicates serious trouble; the obstruction must be located and removed. In excavating for obstructions care should be exercised to prevent fouling the porous material over the drains. The excavation should be backfilled with permeable material as described in B-II-9. Any tendency toward further development of water pockets or soft spots and heaving should be studied, and test holes dug to determine direct cause of failure. If failure caused by defect in pipe drains occurs, immediate repairs should be made. If heaving is due to obstinate water pockets or soft spots that are not tapped with laterals, additional laterals should be installed.

### French or Rock Drains

1. **Outlets:** Screens covering ends of drain pipes in rock drains should be kept in place to prevent small animals from entering.

2. **Outlet ditches:** When a ditch is necessary to provide an outlet for the rock drain, it should be well maintained to prevent silting and provide a rapid get away of the water flow from the drain.

3. **Silting:** To avoid silting of the voids in rock drains the embankment adjacent to the drains should be built up or raised to direct drainage away from them.

## (III) SPECIAL PROBLEMS OF MAINTENANCE

### SOFT SPOTS AND WATER POCKETS

#### 1. Occurrence

Soft spots and water pockets have existed for many years and in certain localities since construction.

They have increased and become more noticeable with increasing density of traffic and the use of heavier equipment.

Soft spots and water pockets exist in localities where soil conditions are unfavorable to satisfactory maintenance, particularly in clay. They will be found in both fills and cuts, but more generally in clay cuts.

Backfill mains and laterals with clean permeable material

### SECTION OF CUT-PIPE DRAINS

### PART PLAN - ROCK AND PIPE DRAINS

### SECTION OR ROCK DRAINS

In soft spots the ballast has generally been beaten down into the roadbed, forming a trough or pockets under the track, the subballast and roadbed being pushed out laterally and oftentimes raised, forming walls which prevent the water draining from the track. This condition invariably results in water pockets.

The usual methods of surfacing and tamping track have no particular effect.

## 2. Importance

The elimination of soft spots and water pockets is of vital importance for safety under present high speed and heavy wheel loads. Higher speeds and heavier wheel loads, with resulting heavy impact, will develop soft spots in roadbeds which have adequately supported lighter loads at lower speeds.

Soft spots and water pockets should be given prompt attention as they soon develop into serious defects. The longer they exist, the more hazardous they become and the greater the resulting maintenance expense, as well as the greater expense involved in providing a permanent remedy.

## 3. Treatment

Soft spots and water pockets result in conditions so nearly alike that the treatment, where it is practicable to remedy the trouble by drainage, is the same.

In cuts a system of pipe drains as outlined in section B-II-9 above is recommended. Test holes should be made at intervals frequent enough to determine accurately the profile of the bottom of the water pockets. Lateral drains should be spaced so as to tap all of the pockets, sixteen feet center to center will usually suffice. The main and laterals should be placed into stable material, with the minimum depth of the main 24 inches and of the lateral 12 inches below the bottom of the deepest pocket, unless the surface of solid rock or hard shale lies at a less depth, in which case the minimum depth of the main can be reduced to 12 inches below the bottom of the deepest pocket. Quite often the "softest" cuts are of a clay material overlying rock or shale. Usually this harder underlying stratum is not on a uniform plane, but is irregular, and if it is uniform it will not conform with the grade of the main. To prevent dislocation of the drain pipe it is well to place the pipe into the rock or shale to at least a depth equal to the pipe's diameter. Other minimum requirements given in B-II-9 should be adhered to.

Frequently single track cuts contain soft spots and water pockets to the extent that lateral displacement or heaving is prevalent on both sides of the track. In this case a subdrain system of mains with laterals should be placed on each side of the track. When one main is used it should be located on the side of the track in which displacement or heaving takes place, which is usually the upper side (with respect to the natural ground surface). If heaving does not occur, the main drain should be placed on the upper side of the track.

Where soft spots cannot be effectively drained, the bearing area of the track structure must be increased.

In fills, French or rock drains as described in section B-II-10 are recommended.

In side hill cut—fill sections, French or rock drains are recommended, supplemented (where it is necessary to intercept water flowing directly from the cut side into the water pockets) by pipe drains on the cut side.

## SLIDES

### Definition

**SLIDE.**—A superficial, gravitational earth movement.

### General

1. Slides usually occur in unconsolidated material, but may occur in open faces of rock formations. Gravity is a primary cause, supplemented by lubricating water, undermining (natural or artificial), clay-type material, certain types of geological structure, or increase of load; and in the case of rock slides specifically, by joint planes, fault planes, schistose structure, or strata dipping towards an open face. In the latter cases, causes are accentuated often by clay seams in partings of the rock.

2. Each slide should be considered as a problem by itself.

3. The cause of the slide should be determined. Thorough and expert examination should be made of soils, drainage conditions and geological conditions related to the cause of the slides. The thickness and volume of the unconsolidated material should be ascertained in order to arrive at a decision as to economic preference between the removal of sliding material and the application of suitable control methods. The removal or prevention of the cause is as important as the restoration of the roadway.

4. Piles or retaining walls for the prevention and cure of slides are not recommended; but their use is permissible for temporary repairs and in special cases.

5. Surface water should be intercepted and diverted by surface ditches described in B-I.

6. Underground water should be drained away, or preferably intercepted at its underground source, and diverted. Slides due to flow of underlying material may be controlled by drainage around the toe of slide by constructing French drains containing perforated pipe. (B-II-10). When this unstable underlying material is deep, tunneling to intercept the flow may be necessary. When feasible, water cut-off is usually more economical and effective than trenching or tunneling. French drains with perforated pipe are sometimes necessary to remove underground water from the slide itself when it is impractical to remove all the sliding material in hillside or "cut" slides. This control method is usually coupled with removal of sliding material, slope modification, and water cut-off, or intercepting drainage.

Fills frequently slide because of water flowing down grade in the ballast pockets, or from adjacent higher ground. Cut off drainage is the prevention. French drains (B-II-10) should be constructed across the upper end of the fill, in the first case, and through the water carrying strata in the latter. Where slides have developed in fills they may be drained and stabilized by constructing French drains, and sometimes supplemented by erecting a berm at the toe of the fill.

To prevent surface water entering fills, a 12" coat of limestone screenings or other impervious material forming a blanket over the top and extending down the slope 10 to 20 feet is successfully used. The lower edge of the blanket should be well keyed in. Fissure filling and oil coating are also sometimes beneficial.

7. Depressions which have formed in unstable ground should be drained and any cracks which may have developed should be filled.

8. Terracing or flattening the slope lightens the load, and may lessen or prevent sliding. This may be done in addition to other methods of control. The removal of the entire moving mass in hillside or slides in cuts may be more economical than control methods.

9. Firmly compacted berms, approximately one-third the height of the fill, will help stabilize the fill and may be used in connection with drainage control methods. Weighting of the toe of a slide is useless if movement exists throughout the mass. When used it must rest upon, or be carried down to solid material.

10. A relocation of the line is sometimes necessary where the slide assumes the proportion of an avalanche.

### Recommendations

The Committee recommends the adoption of this report for publication in the Manual, making the following changes in the 1929 Manual:

Page 23. Remove definition of slide.

Page 25. Under "Drainage" add definition: French Drain—Underground passages for water through the interstices among stone placed loosely in a trench.

Make the following revision to "Specifications for the Formation of the Roadway", pp. 28 to 36, inclusive.

Page 31. Add the following to Section 30, "Intercepting Ditches": "The material excavated from the ditch shall be deposited on the side of the ditch towards the cut, unless otherwise directed. The slope of the waste bank from its summit towards the ditch shall be as long as feasible. In crossing light depressions in hillsides, when directed, levees shall be constructed and the depression filled above the levee so as to bring its surface up to the grade of the ditch. The top surface of this fill shall be of puddled clay.

"Intercepting ditches, when ordered, shall be made on the upper side of the fills where the ground slopes towards the embankment. The cross-sections and locations of such ditches shall be designated. Unless otherwise ordered, the waste dirt shall be placed so as to provide a slope from the toe of embankment to the ditch. If required, they shall be excavated in advance of the construction of the embankment."

Pages 31 and 32. Replace all of Section 32, "Subdrains", with the following:

"Pipe subdrains shall be constructed of the material and size and in the location shown on the plans, or as directed, and to the depth and grade established for them. The cross-section of the trenches shall conform with the plans, and the trench shall be excavated and the pipe laid to true line and grade. Sufficient cribbing or shoring must be used to prevent caving of the trench excavations. All trenches shall be backfilled with an approved permeable material, kept free from dirt, dust and other foreign material. The finished section of the backfill shall conform with the plans."

Page 33. Add the following to Section 40, "Finishing Subgrade": "It must be maintained in this condition until the ballast is placed, (or until accepted). Any back-filling necessary to make a smooth surface shall be made of the same material as exists in the roadbed."

"Where roadbed, in either cuts or fills, is composed of a more or less clay material, all construction tracks shall be removed after the work has been brought to grade and the subgrade rolled with a road roller weighing about 10 tons and thus brought to proper crown and surface."

Page 40. Remove all material under "Slides", Articles 1 to 12, inclusive.

Page 41. Replace Figure 2 with two plates illustrating roadbed drainage.

Page 46. Remove "Means for Prevention or Cure of Water Pockets in Roadbed", Articles 1 to 6, inclusive.

Page 50. Remove all material under "Soft Spots".

Pages 50, 51 and 52. Remove all material under "Ditching".

## Appendix B

### (4) PRACTICE OF JACKING CULVERT PIPE THROUGH FILLS

J. A. Noble, Chairman, Sub-Committee; J. B. Akers, A. A. Cross, L. J. Drumeller, J. N. Grim, G. E. Ladd, R. H. Pinkham, C. S. Robinson, L. S. Rose, W. C. Swartout, O. H. Wainscott.

This report is based on information secured from the following railways: Atlantic Coast Line, Atchison, Topeka & Santa Fe (Photograph 3), Baltimore & Ohio, Bessemer & Lake Erie (Photograph 4), Canadian National, Chesapeake & Ohio, Chicago, Burlington & Quincy, Central of New Jersey, Central of Georgia, Erie, Great Northern, Illinois Central, Louisville & Nashville, Maine Central, Minneapolis, St. Paul & Sault Ste. Marie, New York Central, Northern Pacific, Reading, St. Louis-San Francisco, Southern, Southern Pacific, Union Pacific, Western Pacific.

Valuable information was also furnished by the Armco Culvert Manufacturers Association, Ingot Iron Railway Products Company (Photographs 1 and 2), The Massey Concrete Products Corporation, and the State Highway Department of Ohio (Photographs 5 and 6).

The Committee recommends that this report be accepted as information and the subject discontinued.

## PRACTICE OF JACKING CULVERT PIPE THROUGH FILLS

The installation of pipe culverts, where conditions are favorable, by pushing them into position with jacks, is safe, fast, and will usually be cheaper than other ways of placing the pipe.

### Kinds of Pipe Suitable for Jacking

The most widely used material for pipes installed by the jacking process has been corrugated iron, but cast iron pipe of the bell and spigot type, also special cast iron pipe has been used, and a considerable quantity of concrete pipe has been installed by this method. The proper kind to be used in any particular case can be determined by a consideration of installation cost, probable life, and maintenance cost.

If corrugated pipe is selected, it should be fabricated especially for jacking from 8 gage metal in lengths convenient to handle, say 12 to 18 feet, and should be punched and matchmarked for field riveted joints. This pipe is made up in multiples of 2 feet, and an extra charge is made for odd lengths. It can be had with the invert paved with asphaltic cement, if it appears probable the life of the pipe will be lengthened thereby.

If cast iron pipe is to be used, Class B will be suitable for most installations. The pipe may be bell end or have a special type of joint. As the latter gives the pipe an unbroken outside surface, it will simplify the jacking procedure.

Concrete pipe is available with special reinforcement and ship-lap joints and presents a smooth outside surface. It is usually made in 6-ft. lengths.

### Size of Pipe

Pipe from 24 inches up to 68 inches in diameter has been placed by jacking, without special boring equipment. Ordinarily 42-inch pipe is the least size which should be used, as smaller sizes are hard to work in and little if anything will be saved by their use.

### Approach Trench

When starting a jacking operation the bank is excavated so that a vertical face is presented to the entering pipe. The most economical length of this approach cut or trench will be determined by the relative costs of jacking and of excavation. Where the fill is high 15 or 20 feet will be about right in most cases. It must, of course, not extend to a point where the stability of the track would be affected. For long lines of pipe it will usually be desirable to place 15 or 20 feet of pipe in open trench on the opposite side of the embankment also, although if the jacking is easy, it may pay to place all of the pipe in this manner. The approach trench is usually excavated by hand, but in some cases a power shovel can be used to good advantage. If concrete or cast iron pipe is being placed it will pay to have a crane to line up or rack the pipe, and one of the crawler type excavators can do this and also dig the approach trench.

### Direction of Jacking

As a general proposition, the pipe should be jacked up-hill to facilitate drainage in case water is encountered in the fill, and to prevent interruptions from storm water. If concrete pipe is used, it is more easily kept on grade if jacked down-hill due to the weight of the pipe constantly tending to work the front end down, however this tendency can be controlled without great difficulty. In some cases shafts are sunk, and the pipe jacked both ways from the shaft. This method simplifies the back-stop problem, and decreases the length of pipe to be jacked.

## Unloading and Lining up the Pipe

Corrugated pipe may be unloaded without special equipment, but concrete and cast iron pipe are best handled with a crane. After being landed alongside the track, the pipe can be rolled to the bottom of the fill by ropes.

Care must be used in handling concrete pipe to prevent its being chipped, and corrugated pipe also should be carefully handled, as it has been punched and matched for field rivets, and if the ends are bent or deformed, extra expense will be incurred for correcting these conditions.

If the pipe to be jacked comes in short lengths, it should be lined up or racked on timbers extending at right angles to the direction of jacking, and placed so that the pipe can be rolled on to the guide timbers in front of the jacks quickly and with little effort. This is not essential if corrugated pipe is used, as the individual sections will be longer.

## The Jacking Set-up

The type of back-stop necessary will depend upon the nature of the ground in which it is set, the length of pipe to be jacked and the character of the material to be penetrated. For average conditions, a back-stop constructed as shown in Fig. 2 will be satisfactory.

Guide timbers which may be of  $7 \times 16$  material are set in the approach trench and carefully placed to line and grade; they should extend to the point where the pipe will enter the fill. If concrete or cast iron pipe is being placed steel angles on the inner edges of the guide timbers will be desirable. This is particularly true if a cutting edge is used on the leading joint of pipe.

Fig. 2 shows the kind of jacking frame ordinarily used. For corrugated and cast iron pipe, four  $6 \times 8$  timbers framed to bear against the end of the pipe and leave sufficient opening for the excavated material to be removed will transmit the pressure from the jacking frame satisfactorily.

For concrete pipe a special jacking head is recommended by the manufacturers of the pipe, the details of its construction being shown in Fig. 3.

For concrete pipe a steel cutting edge or shoe is sometimes used, although if annular this is of doubtful value owing to the tendency of the pipe to dig into the bottom of the bore. A special sled-like shoe has been bolted to the lower part of the leading joint of pipe in some cases, and this will prevent the pipe from working below grade. The progress of the pipe, where such a shoe is used, must be carefully watched to prevent it getting above grade. A cutting edge is not necessary for corrugated iron pipe.

## Jacks Required

The number of jacks required and their capacity depend upon the size and length of pipe to be jacked and the nature of the embankment material. For the average job two 15 ton track jacks and two 50 or 75 ton high speed ball bearing high lift jacks should be provided. The operation can be started with small capacity jacks and they will be useful for taking up the compression in the blocking after the jacking gets too heavy for them. To avoid frequent re-setting, the jacks should have not less than a 12 inch lift. On account of the greater weight involved, higher capacity jacks will be required for placing concrete and cast iron pipe than for corrugated pipe.

FIG. 1.

FIG. 3.—Showing Wood Jacking Head for Concrete Pipe.

## Force

The number of men required for an average job will be about as follows:

- 1 Foreman,
- 1 Man digging,
- 1 Loading dirt into the wheel barrow or whatever is used for disposal,
- 1 Man taking waste material away,
- 2 Men operating jacks.

Where progress is rapid, an additional man will be needed to help remove spoil, and in heavy ground or on long lines of pipe two men on each jack will expedite the work.

This force will place from 10 to 16 feet of pipe per eight hour day under favorable conditions.

## Jacking Procedure

The preliminary work, such as constructing back-stop, jacking frame, placing of guide timbers and excavation of approach trench having been done, the work proceeds in the manner described in the following: A joint of pipe is rolled on to the guide timbers and jacked against the bank. Digging is then begun from inside the pipe, the excavated bore being made to grade at bottom, and about one inch larger than the pipe on sides and top. The man digging casts the spoil back into the pipe whence it is loaded into a wheel barrow or car by his assistant. Another man wheels the spoil out through the pipe to the waste bank. It will sometimes be necessary to have an additional man to help pull the loaded barrow up the incline out of the pipe. Where two barrows are being used, the man handling the ingoing barrow helps his partner up the incline. The jacking goes forward continuously until the limit of travel of the jacks is reached. Additional blocking is then placed and the process continued until there is room for another joint of pipe.

The grade and line of the pipe must be carefully watched and corrected when necessary. This can be done by wooden wedges. If available, an engineer's transit will be the most satisfactory way to keep the pipe properly lined up, but sufficiently accurate work can be done with a straight edge and spirit level if care is taken in using them.

## Joining the Pipe

Corrugated pipe is joined by riveting the various sections together as each additional one is rolled into place. To accomplish this, a trench about one foot wide and one foot deep at right angles to line of jacking is necessary. The usual location of this trench is shown in Fig. 1. Corrugated bands are sometimes used at the joints and will ordinarily be preferable on the inside. Rivets can be driven cold, but better results will be secured if they are heated.

If the pipe is of concrete with ship-lap joints, some form of cushioning between the joints will reduce the likelihood of breakage due to concentrated pressure. A piece of  $\frac{1}{2}$  inch Manila rope stuck to the pipe with some form of asphaltic cement will be satisfactory for this purpose. After the pipe is in final position, the joints can be grouted.

Cast iron pipe of the bell and spigot type requires no special provision for joints. If it appears desirable after pipe is in place, the joints can be grouted or filled with asphaltic cement.

## Digging Methods

The tools commonly employed for digging are short-handled picks and shovels. In some soils an adze will be found useful. Compressed air diggers can frequently be

used to good advantage, and where rock or shale is encountered, air drills will be needed. In long pipes, the exhaust from air tools is of value in ventilating the pipe.

The distance to which excavation can be carried ahead of the pipe will depend upon the character of the ground and depth below the track. In very favorable soil the distance may be as much as 4 feet. Ordinarily it will be one or two feet. It is dangerous to carry excavation further ahead of the pipe than is absolutely necessary.

In short pipes of large diameter, artificial light will not be necessary, but in most installations the work will be expedited by the provision of ample illumination. Oil lanterns are largely used, but if available electric lamps will be found more satisfactory.

### Waste Disposal

Where the diameter of the pipe permits, spoil is generally handled from the pipe by wheel barrows. One barrow will be enough for short pipes; 2 will be desirable for long pipes where the jacking proceeds at the rate of one foot or more per hour.

Another method of removing spoil is to load it into a flat-bottom box equipped with wheels, which is pulled back and forth by means of a rope. This box is emptied into a wheel barrow at the end of the pipe, and the spoil wheeled away to the waste bank.

### Procedure in Unstable Soils

The jacking method is not well adapted to placing pipe in unstable soils, and before undertaking an operation of this kind a very thorough investigation of conditions should be made. Borings into the fill where there is doubt as to the nature of the material may be desirable.

If jacking is decided upon it will probably pay to prosecute the work continuously to minimize the tendency of the material to freeze around the pipe.

The excavation should not be carried more than a few inches ahead of the pipe.

Wet sandy soils can be de-watered by means of well points with probably beneficial results.

If the pipe sticks, it may have to be jacked from both ends and possibly from intermediate shafts. The resistance to jacking, caused by material settling in the corrugations of corrugated pipe can be reduced by riveting strips of sheet iron lengthwise on the exterior.

The approach trench should be properly sheeted and braced on the sides and working face.

For obvious reasons bell and spigot type pipe will not be as suitable for placing in unstable soils, as that presenting a smooth exterior.

### Protection of Pipe Against Percolation and Scour

If it is anticipated that the pipe will discharge under head for any considerable period, and particularly if it lies in easily eroded material, the same precautions against percolation along the outside should be taken, as in the case of conduits through earth dams.

Concrete collars or cut-off walls will be found effective for this purpose. It will likely be impracticable to place more than two of these on one pipe due to the amount of excavation and other difficulties involved. The collars therefore should be made larger than if they were built at closer intervals. In addition concrete pavement on the upstream end extending beyond the limits of the open excavation and tied in to the pipe headwall will add to the security of the installation. If the fill does not settle around the pipe the resulting space may be filled with a mixture of mud and cement, about one sack of the latter to the cubic yard.

In extreme cases outlet works for dissipating the energy of the issuing water will be justified.

In all installations, the back-fill at each end should be well rammed around the pipe, and sometimes the excavation for the last joint of pipe can be made slightly smaller than the pipe, thus increasing the resistance to percolation.

If it is necessary to protect the ends against scour, it can be done by concrete pavement or riprap, except that as mentioned in the foregoing, extreme cases will require more extensive protection.

#### Conclusions

The conclusions of the Committee are that where conditions are suitable, the placing of pipe culverts by the jacking process is feasible and will save from 30% to 50% of the cost of placing the pipe by the open trench method and will be cheaper than tunneling. Pipes have been installed by this process in practically all types of material from rock to quicksand. The advantages of the method are:

1. Usually lower cost,
2. No interruption of traffic,
3. Minimum disturbance of roadbed, and consequently little or no subsequent settlement.

This method is particularly applicable where more than one track is involved, where the fill is high, where the material to be penetrated is clay or similar soil that will arch or stand up well and where the traffic is heavy.

Costs will be higher, although not necessarily prohibitive in unstable soils and embankments containing boulders, stumps, waste from rock cuts, or similar obstructions.

Before it is decided that jacking is the proper method to use, all conditions involved in the operation should be investigated, and if the economy to be obtained appears doubtful, cost estimates for open cut placement or tunneling should be compared with the probable cost for jacking. Such estimates should include expense due to interference with traffic, and excess maintenance until embankment becomes stabilized. Generally, jacking operations will have little or no effect upon the stability of the track, and if subsequent settlement is experienced, it will be very slight.

## Appendix C

## (5) BEARING POWER AND OTHER PHYSICAL PROPERTIES OF SOILS, INCLUDING EFFECT UPON ROADBED

H. W. Legro, Chairman, Sub-Committee; J. B. Akers, G. H. Burnette, Paul Chipman, L. C. Frohman, C. T. Jackson, G. E. Ladd, W. J. Lank, E. R. Lewis, Roscoe Owen, L. S. Rose, J. B. Trenholm.

The scope of the subject was enlarged this year by assignment of the broader field of the bearing power and other physical properties of soils in addition to consideration of their effect on roadbed performance.

Advanced interest in the relation of the physical properties of soils to the settlement of foundations of structures and to the subgrade performance of transportation ways has been manifest during the past decade. Soil research by laboratory and field tests, revealing hitherto unrecognized effects of certain properties on the stability of supported structures, has stimulated this interest. Investigators are far from agreeing as to the application of the knowledge thus far gained, but there is general agreement that many of the concepts that have governed the use of soils to carry loads require revision.

There is a fairly extensive bibliography covering recent investigations, mostly along laboratory and highly technical lines, and a sad lack of recorded experience with foundation loads in terms of an adequate description of the soils encountered. The Committee is attempting practical evaluation of the results and partial conclusions recorded, but pending further study is not ready to do more this year than indicate some respects in which soil engineering is undergoing change, and to include a glossary of soil terms as a guide to identification of the field characteristics of the soil material as found in its natural state.

The present practice of selecting the admissible soil pressure under footings, slabs, etc., from tables given in building codes ignores factors that appear important to many engineers as influencing settlements; for example, the size and shape of the loaded area and the depth of the foundation below the surface of the ground. Tests reported\* indicate that for cohesive soils (such as clays), the settlement produced by a given load per unit of area may increase almost in direct proportion with the diameter of the loaded area. For cohesionless soils (such as sands), it has been observed that the size of the area has little effect.

Settlement is also dependent on the depth of the foundation, i. e., the greater the depth, normally the greater the bearing power, more especially of cohesive soils, due to natural pre-consolidation by the pressure of the overlying soil.

Observations of differences in the behavior of foundation piles under driving and under static load, and of an individual pile as compared with a group, have led to critical discussion of pile-driving formulas in present use.

Few, if any, investigators of the behavior of soils have yet attempted definite conclusions in the matters of the preceding paragraphs.

The terminology of soils given here is presented as a preliminary listing of soil characteristics. With some modifications, it is taken from a report\* by W. I. Watkins and Henry Aaron of the U. S. Department of Agriculture, who compiled the terms largely from a report of the Committee on terminology of the American Soil Survey Association at its eighth annual meeting, March, 1928.

## TERMS IDENTIFYING SOILS

## SOIL MAP TERMS

**SOIL PROFILE.**—A vertical section of the soil layers from the surface into the underlying unweathered material.

**SOIL HORIZON.**—A layer or portion of the soil profile more or less well defined in appearance or other characteristics.

**SOIL CLASS.**—A classification of soils based on texture only, as sand, sandy loam, clay, etc. It is determined in the field by the appearance and feel, and in the laboratory by mechanical analysis; textural grade.

**SOIL TYPE.**—A soil which over the full extent of its occurrence has relatively uniform texture of the surface soil and relatively uniform profile characteristics in the upper horizons; the unit of soil mapping. The name of the soil type is a combination of a series name and the class designation, as for example, Orangeburg sandy loam.

**SOIL SERIES.**—A group of soil types that have profiles (of the upper horizons) closely similar in all respects except the texture of the surface layer.

## TEXTURE

Texture is a term indicating the size of the individual soil grains or particles and the proportions of material of each size present in any given case.

As the soil is usually made up of particles of widely varying size, the textural terms express the average effect or the combined effect of all these grain sizes. They may indicate the predominance (in quantity or in textural effect) of a certain group of grains.

Texture is determined by mechanical analysis, a laboratory process of separating the soil into groups of grain sizes. The system of mechanical analysis used by the U.S. Bureau of Chemistry and Soils separates the soil material into seven grain sizes or "separates" having the following sizes and names:

- 2 to 1 millimeter, fine gravel
- 1 to 0.5 millimeter, coarse sand
- 0.5 to 0.25 millimeter, sand
- 0.25 to 0.10 millimeter, fine sand
- 0.10 to 0.05 millimeter, very fine sand
- 0.05 to 0.005 millimeter, silt
- Below 0.005 millimeter, clay

In the following paragraphs are given the proportions of certain of the grain sizes found in the major soil textures:

Sands contain less than 20 per cent of silt and clay. (Include coarse, fine, and very fine sands.)

Sandy loams contain from 20 per cent to 50 per cent of silt and clay but do not have over 20 per cent of clay. (Include coarse, fine, and very fine sandy loams.)

Loams have more than 50 per cent of silt and clay combined, but have less than 50 per cent of silt and less than 20 per cent of clay.

Silt loams have more than 50 per cent of silt and less than 20 per cent of clay.

Clay loams have more than 50 per cent of silt and clay combined but less than 50 per cent of silt and between 20 per cent and 30 per cent of clay. (Include sandy clay loams, clay loams, and silty clay loams.)

Clays have more than 50 per cent of silt and clay combined and more than 30 per cent of clay. (Include sandy clays and silty clays.)

In the field, texture is determined by the feel of the soil mass when rubbed between the fingers. The following statements give the obvious physical characteristics of the basic textural groups:

**SAND.**—Sand is loose and granular. The individual grains can readily be seen or felt. Squeezed in the hand when dry it will fall apart when the pressure is released. Squeezed when moist, it will form a cast, but will crumble when touched.

**SANDY LOAM.**—A sandy loam is a soil containing much sand but having enough silt and clay to make it somewhat coherent. The individual sand grains can readily be seen and felt. Squeezed when dry, it will form a cast which will readily fall apart, but if squeezed when moist a cast can be formed that will bear careful handling without breaking.

Sands and sandy loams are classed as coarse, medium, fine, or very fine, depending on the proportion of the different sized particles that are present.

**LOAM.**—A loam is a soil having a relatively even mixture of the different grades of sand and of silt and clay. It is mellow with a somewhat gritty feel, yet fairly smooth and slightly plastic. Squeezed when dry, it will form a cast that will bear careful handling, while the cast formed by squeezing the moist soil can be handled freely without breaking.

**SILT LOAM.**—A silt loam is a soil having a moderate amount of the fine grades of sand and only a small amount of clay, over half of the particles being of the size called "silt." When dry it may appear quite cloddy, but the lumps can be readily broken, and when pulverized it feels soft and floury. When wet the soil readily runs together and puddles. Either dry or moist it will form casts that can be freely handled without breaking. If squeezed between the thumb and finger it will not "ribbon" but will give a broken appearance.

**CLAY LOAM.**—A clay loam is a fine-textured soil which breaks into clods or lumps that are hard when dry. When the moist soil is pinched between the thumb and finger it will form a thin ribbon which will break readily, barely sustaining its own weight. The moist soil is plastic and will form a cast that will bear much handling. When kneaded in the hand it does not crumble readily but tends to work into a heavy compact mass.

**CLAY.**—A clay is a fine-textured soil that forms very hard lumps or clods when dry. When the moist soil is pinched out between the thumb and fingers it will form a long, flexible ribbon.

**GRAVELLY OR STONY SOILS.**—All of the above classes of soils, if mixed with a considerable amount of gravel or stone, may be classed as gravelly sandy loams, gravelly clays, etc., as stony sandy loams, stony loams, etc., or as sandy clay loams, sandy clays, etc.

**COLLOIDS (Soil).**—Constituents of the soil having a particle size indicated by an average diameter not greater than 0.001 millimeter (1 micron), as designated by the U.S. Department of Agriculture, derived from the weathering and decomposition of soil minerals, together with organic matter, and greatly influencing the characteristics of the soil mass with which it is intimately associated, for example—cohesiveness.

**PEAT SOIL.**—Composed predominantly of organic material highly fibrous, with easily recognized plant remains.

**MUCK SOIL.**—Composed of thoroughly decomposed black organic material, with a considerable amount of mineral soil material, finely divided and with a few fibrous remains.

**LEAF MOLD.**—The accumulation on the soil surface of more or less decomposed organic remains, usually the leaves of trees and remains of herbaceous plants; the A, or surface, horizon.

**FLOURY.**—Fine-textured soil consisting predominantly of silt (or flocculated clay with aggregates of silt size) which when dry is incoherent, smooth, and dust-like.

**GRITTY.**—Containing a sufficient amount of angular grains of coarse sand or fine gravel, so that these dominate the "feel." Usually applied to medium-textured soils (loams) where the actual quantity of these coarse grains is rather small.

**HEAVY (textured).**—Applied to soils of fine texture in which clay predominates, with dense structure and firm to compact consistency. The term is also applied to soils containing a somewhat higher proportion of the finer separates than is typical of that textural class (as a "heavy sandy loam.")

**LIGHT (textured).**—Applied to soils of coarse to medium texture with a very low silt and clay content, incoherent, single-grained structure, and loose consistency. The term is also applied to soils containing somewhat higher proportions of the coarser separates than is typical of that textural class (as a "light loam.")

**SHARP.**—Containing angular particles in sufficient amount to dominate the "feel".  
**Abrasive.**

**SMOOTH.**—Containing well-rounded coarser particles and a predominance of the finer separates. Not abrasive.

## STRUCTURE

The term "soil structure" expresses the arrangement of the individual grains and aggregates that make up the soil mass. The structure may refer to the natural arrangement of the soil when in place and undisturbed (as structural profile) or to the soil at any degree of disturbance. The terms used indicate the character of the arrangement, the general shape and the size of the aggregates, and in some cases may indicate the consistence of those aggregates.

**ADOBE STRUCTURE.**—This term describes a soil which on drying cracks and breaks into irregular but roughly cubical blocks. The cracks are usually wide and deep and the blocks are from 20 to 50 or more centimeters across. (Adobe soils are usually heavy-textured and high in content of colloidal clay.)

**AMORPHOUS STRUCTURE.**—A soil of fine texture having a massive or uniform arrangement of particles throughout the horizon. Structureless. Found only in soils of finest texture, where individual grains cannot be recognized.

**BUCKSHOT STRUCTURE.**—Aggregates of roughly spherical shape, usually two or three millimeters in diameter, and of a hard consistence.

**CLOD (or cloddy) STRUCTURE.**—Aggregates of irregular, angular shape, usually 4 centimeters or more in diameter and of a hard consistence.

**FINE CLODDY STRUCTURE.**—When most of the clods are close to the minimum size.

**COARSE CLODDY STRUCTURE.**—When most of the clods are 10 centimeters or more in diameter.

**COLUMNAR STRUCTURE.**—A natural arrangement of the soil mass in more or less regular columns separated by vertical cleavage lines, and usually broken by horizontal cracks into sections with longer vertical than horizontal axes.

**CRUMB STRUCTURE.**—Porous aggregates of irregular shape, rarely over 2 centimeters in diameter and of a medium to soft consistence.

**FINE CRUMB STRUCTURE.**—Crumbs 5 millimeters or less in diameter.

**COARSE CRUMB STRUCTURE.**—Crumbs 2 centimeters or more in diameter.

**CRUST (or crusted) STRUCTURE.**—This term is used where the upper or surface horizon coheres into plate or crust distinct from the horizon immediately below it.

**CRUST-MULCH STRUCTURE.**—An arrangement where a surface crust is underlain by an horizon of loose, incoherent particles of mealy, crumb, or granular structure.

**DENSE STRUCTURE.**—Having a minimum of pore space and an absence of any large pores or cracks. Approaching amorphous.

**FLUFFY STRUCTURE.**—A surface condition where the aggregates are loose, of light weight and fine texture, with no cohesion or evidence of arrangement; floury.

**GRANULAR STRUCTURE.**—Aggregates varying in size to 2 centimeters in diameter, of medium consistency, and more or less subangular or rounded in shape.

**FINE GRANULAR STRUCTURE.**—Aggregates under 5 millimeters diameter.

**COARSE GRANULAR STRUCTURE.**—Aggregates close to maximum size.

**HARDPAN.**—An horizon of accumulation that has been thoroughly cemented to an indurated, rock-like layer that will not soften when wet. The term hardpan is not properly applied to hard clay layers that are not cemented, nor to those layers that may seem indurated when dry, but which soften and lose their rock-like character when soaked in water. The true hardpan is cemented by materials that are not readily soluble, and is a hard layer that definitely and permanently (in nature) limits downward movement of roots and water.

**CLAY PAN.**—An horizon of accumulation or a stratum of stiff, compact and relatively impervious clay. The clay pan is not cemented, and if immersed in water can be worked to a soft mass. Its presence may interfere with water movement or root development the same as a true hardpan. It is more difficult to overcome, for, whereas a hardpan can be shattered by explosives, the clay pan, after breaking by any means, will run together and re-form as soon as thoroughly wetted. The distinction between hardpan and clay pan is an important one in the soil classification.

**LAMINATED STRUCTURE.**—An arrangement of the soil mass in very thin plates or layers, less than 1 millimeter in thickness, lying horizontal or parallel to the soil surface.

**MASSIVE STRUCTURE.**—A soil mass showing no evidence of any distinct arrangement of the soil particles. Structureless. May be found in soils of any texture.

**MEALY STRUCTURE.**—A crumb-like structure in which the aggregates are of soft to very soft consistency and usually less than 5 millimeters in diameter.

**NUT STRUCTURE.**—Compact aggregates, more or less rounded in shape, of hard to medium consistency, and from one-half to 4 centimeters in diameter.

**FINE NUT STRUCTURE.**—Aggregates below 1 centimeter in diameter.

**COARSE NUT STRUCTURE.**—Aggregates over 3 centimeters in diameter.

**PLATE (or platy) STRUCTURE.**—An arrangement of the soil mass in plates or layers 1 to 5 millimeters or more in thickness, lying horizontal or parallel to the soil surface.

**SINGLE-GRAINED STRUCTURE.**—An incoherent condition of the soil mass with no arrangement of the individual particles into aggregates. Structureless. Usually found in soils of coarse texture.

**STRUCTURELESS.**—Without any discernible structure or arrangement of the soil particles into aggregates. This condition is better expressed by the terms, single-grained, massive, amorphous, etc.

**VESICULAR STRUCTURE.**—A soil horizon or soil aggregate containing many small rounded cavities smooth on the inside as though formed by gas bubbles.

## CONSISTENCE

“Soil consistence” is a term expressing the degree of cohesion of the soil particles and the resistance offered to forces tending to deform or rupture the aggregates. Consistence and structure are closely related and frequently interdependent. The terms expressing consistence and structure are distinct, however, and need not be confused or used with double meaning.

**BRITTLE.**—A soil which when dry will break with a sharp, clean fracture. If struck a sharp blow, it will shatter into cleanly broken hard fragments.

**MELLOW.**—Soil particles or aggregates are weakly adhered in a rather porous mass, readily yielding to forces causing rupture. A consistence softer than friable. Without tendency to pack.

**PLASTIC.**—Readily deformed without rupture. Pliable but cohesive. Can be readily molded. Puttylike. This term applies to those soils in which at certain stages of moisture the grains will readily slip over each other without the mass cracking or breaking apart.

**SOFT.**—Yielding readily to any force causing rupture or deformation. Aggregates readily crushed between fingers.

**STICKY.**—Applied to soils showing a decided tendency when wet to adhere to other materials and foreign objects.

**FIRM.**—Resistant to forces tending to produce rupture or deformation. Moderately hard. Aggregates can be broken between fingers.

**FRIABLE.**—Aggregates readily ruptured and crushed with application of moderate force. Easily pulverized or reduced to crumb or granular structure.

**HARD.**—Resistant to forces tending to cause rupture or deformation. Difficult or impossible to crush aggregate with fingers only.

**TENACIOUS.**—Soils showing a decided resistance to rupture. Soil mass adheres firmly.

The terms "sticky" and "tenacious" are often used as synonyms, but in soil usage the former is taken to refer to adhesion, the latter to cohesion. Both terms may be applicable to a soil at the same time.

**STIFF.**—Resistant to rupture or deformation. A soil stratum or horizon that is firm and tenacious, and tending toward imperviousness. Usually applied to condition of the soil in place and when moderately wet.

**TIGHT.**—A stratum or horizon that is compact, impervious and tenacious and usually plastic.

**TOUGH.**—Resistant to rupture. Tenacious. A stratum or horizon that can be readily bored into with the auger but which requires much force in breaking loose and pulling out the core of soil.

## COMPACTNESS

Compactness is the degree of resistance offered by a soil to the penetration of a pointed instrument.

**IMPERVIOUS.**—Highly resistant to penetration by water and usually resistant to penetration by air and plant roots. Impenetrable. In field practice the term is applied to strata or horizons that are very slowly penetrated by water and that retard or restrict root penetration.

**INDURATED.**—(See under cementation).

**LOOSE.**—Soil particles or small aggregates are independent of each other or cohere very weakly with a maximum of pore space and a minimum resistance to forces tending to cause rupture.

**CHEESY.**—Having a more or less elastic character, deforming considerably without rupture, yet broken without difficulty or the application of much force. (Characteristic of certain highly colloidal soils when thoroughly wet.)

**COMPACT.**—The soil packed together in a dense, firm mass, but without any cementation. Noticeably resistant to forces tending to cause rupture or deformation. Coherent. Hard. Relative degree of compactness may be expressed by terms as slightly compact, very compact, etc.

## CEMENTATION

**CEMENTATION.**—A condition occurring when the soil grains or aggregates are caused to adhere firmly and are bound together by some material that acts as a cementing agent (as colloidal clay, iron or aluminum hydrates, lime carbonate, etc.).

The degree of cementation or the persistence of the cementation when the soil is wetted should be stated. Some terms indicate the permanence, as "indurated," "hardpan," etc.

**FIRMLY CEMENTED.**—Cementing material of considerable strength requiring considerable force to rupture the mass. Usually breaks, with clean though irregular fractures, into hard fragments.

**INDURATED.**—Cemented into a very hard mass which will not soften or lose its firmness when wet, and which requires much force to cause breakage. Rock-like.

**WEAKLY CEMENTED.**—Term applied when cementing material is not strong, and the aggregates can be readily broken into fragments with a more or less clean fracture.

**SOFTLY CEMENTED.**—Term applied when cementing material is not strong nor evenly diffused throughout the mass. Aggregates are readily crushed, but do not break with a clean fracture.

## Appendix D

### (6) METHODS OF PROTECTING AGAINST DRIFTING SNOW AND OPENING SNOW BLOCKADES

F. W. Hillman, Chairman, Sub-Committee; Paul Chipman, G. B. Farlow, P. D. Fitzpatrick, J. A. Given, E. M. Smith, J. C. Wallace, F. E. Wiesner.

Last year this Committee presented a report on "Methods of Protecting Against Drifting Snow and of Removal of Snow on the Line and in Yards and Terminals" as information, with a recommendation that this subject be reassigned so that the material now contained in the Manual ("Snow Fences, Snow Sheds and Recommended Methods of Snow Removal", pages 73 to 76, inclusive, adopted 1909, 1910, 1915) might be revised in the light of the 1933 report and comments thereon. In the reassignment there was a modification made in it, as indicated in the title above, with a further requirement for collaboration with Committee XXVII—Maintenance of Way Work Equipment. Accordingly, the following report, prepared in collaboration with Committee XXVII, is offered for publication in the Manual to replace the present material referred to above.

### PROTECTION AGAINST DRIFTING SNOW

Snow is carried by the wind close to the surface of the ground and is deposited in drifts whenever the velocity of the wind is reduced or eddies are formed by obstructions or by sudden changes in the configuration of the surface, such as railway cuts.

Brush, trees, buildings and other obstructions which cause snow to be deposited in drifts on tracks should be removed where economically justifiable.

Drifting of snow in shallow cuts may be prevented or alleviated by either raising the tracks and eliminating cut or reducing slopes on both sides to 4 to 1 or flatter. Other cuts may be widened to provide a place for the snow to accumulate.

Where none of these remedies are practicable or effective, consideration must be given to placing snow fences in the path of the wind so as to form artificial eddies on the windward side of the track and far enough away to cause the snow to be deposited before it reaches the track.

The location of the drift or eddy depends upon the form of the fence. A tight fence of sufficient height causes the snow to accumulate on the windward side of the fence; an open fence causes the snow to accumulate principally on the leeward side. The distance between the drift and the fence depends upon the height of the fence, the width of the openings between the solid members, the velocity of the wind and the character of the snow.

The type of snow fence and its location for the protection of a definite stretch of track depends largely upon local conditions, which may vary from year to year. These can be determined only from experience. For this reason portable snow fences are recommended generally for an initial installation.

Portable snow fences of the type shown on a following page, are frequently used. A similar fence of steel construction also is available. However, this type of fence is being replaced by the lighter slat and wire type, which can be rolled up, moved and quickly re-erected. When necessary to resist high winds, this type may be guyed with wire to bolts or stakes driven into the ground. If the location is one where the fence may have to be raised due to snow piling up, long posts should be used.

Portable fences usually are erected in the fields adjoining the right-of-way. They should be set on the windward side of the track at right angles to the prevailing winds; to provide for variations in the direction of the wind, it is sometimes necessary to set the fence in crescent form. The topography for some distance away from the track has such a bearing on the action of the wind that sections otherwise similar cannot always adequately be protected with the same type of fence set the same distance out. For ordinary conditions one line of fence is sufficient. The quantity of snow sometimes, however, requires additional lines of portable snow fences set parallel and spaced about 100 feet apart.

Where experience indicates that the right-of-way is wide enough and other local conditions permit, a snow fence of a fixed type may be used, frequently serving also as right-of-way fence.

The most generally used types of fixed fence are shown on a following page. Where the right-of-way line is 50 feet or less from the center of the nearest track, a fence with the boards laid close should be used. For greater distances, space should be provided between the boards; at a distance of 100 ft., the openings should be 50 per cent of the area of the fence. The height of fixed board fences depends upon the probable amount of snow.

Trees and shrubs properly selected for adaptability to climate, properly planted and cared for, afford an effective protection in some localities against drifting snow, and at the same time serve to improve the appearance of the right-of-way.

Stone walls may be used for snow barriers where suitable and sufficient stones for dry masonry walls are available.

Storms differ so much in their intensity and action from year to year that it will generally be found uneconomical to build a fixed fence to afford protection against the severest storms. The fixed fence should be built as a first line defense against the average storm. Portable fences of a type which can be quickly erected should be depended on for second and third line defense, as experience demonstrates the need.

In emergencies, snow can be thrown up by hand into banks or ridges back of fixed or portable fences as an added line of defense.

In localities which require protection from mountain snow slides, snow sheds are necessary to furnish adequate protection. These are expensive to construct and maintain and should be constructed of durable materials. The railway should be so located, if practicable, as to make snow sheds unnecessary.

## PERMANENT SNOW FENCE

## OPEN BOARDING

## CLOSE BOARDING

# PORTABLE SNOW FENCE

In cuts from 25 feet to 30 feet deep where it is not economical or practicable to widen the cut, timber snow sheds are sometimes constructed to advantage. In these the roof extends over entire width of cut and are designated as prairie type snow sheds. They are much lighter in construction than the heavy mountain type which are designed to resist snow slides.

## OPENING SNOW BLOCKADES

### General

Keeping a railway line open in territory subject to heavy snows requires watchfulness, orderliness and forethought. In the fall all snow equipment and accessories should be tested and made ready for emergency use. A general program should be formulated for stationing snow fighting equipment at vantage points, outlining a general supervisory plan, and determining methods by which men are to be secured, protected from hazards attending snow storms, fed and relieved.

Meteorological reports should be made available for general and division officers and local officers should be kept well informed of the progress of approaching storms.

It is desirable to keep ahead of storms and not let the line become blocked. To get best results it is essential that snow plows be started from terminals before the storm actually breaks and, in severe storms, additional plows despatched at such intervals as will preclude the formation of snow banks that cannot be moved with plows, possibly following up with a locomotive to pull out the plow or its engine or both if they get stalled or derailed. Prompt clearance of cuts before further snow or wind storms is quite necessary. It is the following storms which generally cause real trouble.

During severe storms, if there is difficulty in keeping the line open, consideration should be given to reducing tonnage, double heading or abandonment of trains and curtailment or complete stopping of yard switching until the storm abates and the line is opened. Stalled trains and dead locomotives add much expense, anxiety and hazard to the work of moving snow and delay opening of blockades.

No definite rule can be established for the use of flangers or plows. Much depends on the moisture content of the snow, formation of drifts and on the available clear space for snow disposal. However, the following suggestions are made as recommended practice:

### On Line

Flangers should be used for the removal of snow where the depth is less than 6 inches over the top of the rail. Flanging of tracks is greatly expedited if the flanger is equipped with scoops for each direction which allow flangeways to be cleared in either direction without turning the flanger. The scoops must in all cases be equipped with lowering and raising device operated from inside of car. Flangers can frequently be used to good advantage by attaching to rear of freight train and thus avoid using an extra train and crew.

The wedge or push plow placed on the pilot of the locomotive is useful for occasional light drifts of up to two or three feet over the top of the rail.

The larger wedge or push plow should be used for removing snow up to 6 or 8 feet deep which cannot be removed by flangers or push plows on locomotive pilots. The effectiveness of these plows is greatly increased if they are equipped with adjustable side wings, which can be used for widening the opening. These plows should be equipped with a coupler on front as well as rear so as to expedite switching of cars off of sidings or yard tracks which must be cleared of snow.

Great care must be exercised in the use of plows placed on the front of loaded ballast or gondola cars to prevent the cutting edge of the plow from riding on the rail and catching at frogs, switches and crossing plank due to the weight of the snow. This can be prevented by a narrow casting placed under the plow near the cutting edge so as to ride on the rail and keep the plow up. Special consideration must be given the designing and placing of this casting if self-guarded frogs are to be encountered. There are combined flangers and plows so designed that this difficulty does not obtain.

Care must be taken in approaching drifts which snow plows will not uniformly contact and cause plow to turn over sidewise. If face of drift is frozen over the rails, it should be broken down or "faced" so that plow will engage the snow and not ride on top of it. If the plow has been stuck and pulled back, the snow may have been compacted to such an extent that it should be broken down before making another charge and possibly causing serious damage to the plow from impact with solid snow.

Ditchers with plow-shaped front make excellent snow movers. The spreader wings can be used to good advantage to widen the cut after it is opened up. Many of these ditchers are equipped with steel teeth set under front edge of the plow which are very effective in cutting up ice which may have formed between and over the rails.

Ice cutter cars have been used with great effectiveness for loosening hard snow and ice which forms in the tracks, especially in yards and on occasions in many miles of tracks. These cars are essentially a box car with end lookout windows and compressed air equipment, by means of which a lever may be moved to raise and lower a plow or V shaped steel plate 1" thick, 6" wide and about 4'9" long placed below the center of the car on edge and between the running rails. To this steel plate 4" apart and extending 6" below its lower edge are bolted tire-steel teeth with points inclined slightly forward. Extra teeth are carried in the car. The cutter must, of course, be raised at turnouts and crossings.

Rotary snow plows are necessary for quick removal of snow where the snowfall has filled deep cuts which cannot be removed with push plow. Attempts to use them in shallow drifts not deep enough for reasonably full contact of wheel may cause the wheel to race under the light load and damage the machinery.

When operating flangers and plows over the line, the problem of keeping ice and snow out of guard rails, frogs and switches is important, particularly in locations where it is difficult for section men to get to them in severe storms. Carbide carried on the plow and placed on the ice will in a short time get sufficient moisture to form gas, which can be ignited; the heat generated will melt the ice. Casing Head gasoline, or Hydrocarbon might also be sprinkled over such places and ignited. Salt can be used also, except in electrified, automatic signal, or train control territory.

### In Yards and Terminals

The method for removal of snow from yards and terminals depends upon the physical layout, the density of traffic and the amount of snow.

If snow is not very deep, possibly it is best not to remove it from tracks, except to make flangeways by hand shoveling, or with flangers, if traffic will permit, and clean out of switches by hand or snow melters. The use of the latter requires good drainage to carry away melted snow or it may freeze and cause more trouble than the snow, or heat must be great enough to evaporate water. Frequently switch engines are equipped with a perforated pipe laid across track under pilot and steam blown through it to clean away snow. If traffic is not too dense, this may be successful, but in dense traffic districts another engine added is often a nuisance. Then, too, if not judiciously used, it

may be simply a case of blowing snow back over places already clean. Casing Head gasoline and Hydrocarbon sprinkled over snow and ignited is also used. Salt should not be used in electrified, automatic signal or train control districts and should be used in other districts only during that portion of winter when snow melts during the day-time and freezes at night.

In clearing yard tracks of heavier falls of snow, it is well to first pull cars off of four tracks; then run a plow down one track and follow with a spreader, pushing the snow clear of adjacent tracks; then run the spreader down the cleared tracks, repeating the operation until the snow is piled too high for further piling. Then start on the other side of the pile and repeat. In some instances, where the yard is not too wide and the snow not too heavy, the entire yard may be cleared with the spreader and picking up the snow avoided. Where this cannot be done, the piles of snow must be left to melt or loaded onto cars either by hand or machinery. With extremely heavy snow falls, the rotary plow may have to be used to open up tracks.

In cleaning snow off station platforms, where snowfall is light, hand methods are probably the cheapest. Small wooden hand push plows are effective. Use should be made of baggage trucks, on which to load and carry away snow. Snow should not be placed on tracks, as passing trains may throw it over passengers waiting on platforms. Where the snowfall is heavy, large horse-drawn scrapers are effective. A supply of sand should be on hand at stations to scatter over platforms in sleeting and freezing weather. Salt should not be used on concrete platforms.

At team yards snow can be pushed to the center or side of driveway with plows either horse-drawn or placed on automobile trucks or tractors. The snow may be left to melt or loaded onto trucks or cars by hand or machinery.

## Appendix E

### (9) METHODS OF PROTECTION AGAINST DRIFTING SAND

C. W. Baldridge, Chairman, Sub-Committee; Paul Chipman, G. B. Farlow, L. C. Frohman, C. T. Jackson, Roscoe Owen, E. M. Smith, H. E. Stansbury, J. B. Trenholm, J. C. Wallace.

Drifting sand, frequently called blow sand, is a source of considerable trouble and much expense to many railways as well as to highways, irrigation and other ditches, etc. Not only is the trouble from drifting sand a present one, but the sand dunes and buried lands, in many localities, and buried cities of the ancient times show that it has been a source of trouble ever since humanity began attempting to build permanent dwellings and permanent works.

The exceedingly dry and windy fall, winter and spring of 1932-33, throughout much of the western half of the United States, brought trouble from drifting sand and earth at many places not previously so affected.

The earliest correspondence on the subject, to fall into the hands of the Committee, is a letter written in 1918 by the Chief Engineer of the A. T. & S. F. Railway, carrying the following information:

"In the earlier days (1901) we experienced trouble around Waynoka (Oklahoma) from drifting sand, mounds at times four and five feet high being deposited on the track, and at times causing delay to traffic, so much so that for sometime we maintained a trackwalker from Waynoka west, I think about seven miles, and which was in the area where the sand mounds existed and shifted considerably.

"No remedy has been found, and it is necessary at times to haul out the accumulated sand by work trains, team work, with scrapers or other methods."

Another letter of interest, written in 1932, also by the Chief Engineer of the A. T. & S. F. Railway, and addressed to Everitt W. Wilson, Acting Director-General and Engineer in Chief of the Southern State Railways, for the Imperial Government of Persia, at Ahwaz, Persia, has the following information:

"We do not have any extreme cases such as you have in Persia, and we are able to cope with this problem with sand fences and hand shoveling. Sometimes we have to use teams and scrapers to carry off the accumulation or use ditching machines. Snow fences in some cases become covered over and then it is necessary to place another fence on top of the pile or in a different location. We have experimented with planting sweet clover to cover sand, but without much success as the seed would be blown away before they could germinate. Our snow fences are usually made of old ties stuck on end, but picket fencing can be used advantageously for this purpose."

Mr. Wilson's reply throws some light on other people's troubles with blowing sand, and they are not all due to the wind:

"Our problem is complicated by the utter lack of all vegetable life and the violence and duration of sandstorms. In some places, we shall undoubtedly be driven to use a sort of corrugated metal tunnel and let the sand blow over it. In other places, we are experimenting with steel cement casks and old oil drums filled with sand and spaced a few feet apart in a line paralleling our tracks a few hundred feet to windward. These rows of obstructions, we hope, will cause sufficient eddy currents to precipitate deposit before reaching our tracks. What we are going to do eventually to rid ourselves of this accumulation of sand remains to be seen. Wooden fences are impracticable because the nomads appropriate every bit of fuel they find, even including cross-ties at times."

Reports of special interest that have come direct to the Committee are quoted as follows:

From Mr. Kirkbride of the Southern Pacific:

"Reference on page 885 of Camp's "Notes on Track" to standard section of roadbed on the Southern Pacific requiring protection against damage by sand storms is to a very old standard which we no longer use, as it was not effective.

"The methods which we do use for controlling sand may be classified under three subdivisions, depending on climatic conditions, as follows:

(1) Along the Pacific Ocean, in certain localities in California and Oregon, the drifting sand from the ocean is controlled by covering the sand dune areas with vegetation. This is accomplished by first planting bent or bunch grass; after this grass has developed a dense and vigorous growth and the sand areas have become still, we follow up with the planting of acacia and similar shrubs, pine and eucalyptus trees. Areas near habitations of the better order are reclaimed by planting mesembryanthemum. The successful growth of such vegetation depends on the moisture from the sea fogs and rains prevalent along the coast.

(2) In semi-arid regions where there is sufficient moisture to grow desert trees such as the athel or tamarisk, rows of such trees are planted at intervals extending out some distance from the track. These raise the air currents permitting a natural vegetation of desert grasses and brush to grow.

(3) In desert territory where the absence of sufficient moisture or other conditions makes tree and grass growth practically impossible, it is deemed best to level down the hummocks, remove all scattering brush and other obstructions such as fence posts, piles of ties, etc., thus permitting the wind to have a free sweep across the track and right-of-way. This permits the sand to move with the wind without piling up.

"Obviously, such methods of sand control require the cooperation of adjacent property owners where land is held in private holdings.

"The athel or tamarisk tree is a native of the Sahara Desert. It is a remarkably fast growing tree and one we find very serviceable in establishing wind breaks around section and station buildings. We use this tree very extensively in Southern California, Arizona and New Mexico."

From Mr. J. Haas of Division Engineer Wagner's forces, Santa Fe Railway, Amarillo, Texas:

"At MP 12 on the NT&SF (Texas) we have attempted to check drifting sand by placing a solid line of old ties on end, placing them in the ground  $1\frac{1}{2}$  to 2 feet and then placing additional rows on top of and behind the first row as sand drifted to the top. We have them now three ties high. This protects the track for awhile, but results in the formation of a sand dune and, of course, requires the removal of sand from time to time from the side of the track by reason of the high bank or "dune" of sand forming and this sort of protection gives only temporary relief.

"On the B&NW at MP 16 (Oklahoma) we had considerable trouble with blow sand covering our tracks several years ago. We attempted to stop it by placing old ties at the right-of-way fence, but found that this method caused the sand to drift and it was forming a rather high sand drift or dune and we removed the old ties and cut out all of the brush and obstructions from the south side of the track to the right-of-way fence and made a uniform surface of the right-of-way where the sand was giving us trouble and then placed a layer of about six inches of clay and hard dirt on the top and smoothed it down. This hard clay was placed a distance of ten feet on each side of the track to the top of the ties and we also filled the track in with it between the rails, giving this about two inches of the hard dirt, which permitted the sand to blow over and away from the track and not lodge or drift as previously. This was done in 1924, since which time we have not been bothered with blow sand on the track at that location.

"At MP 14 on the B&NW branch (Oklahoma) we have a mountain of blow sand which accumulates to a depth of 15 feet up to our tracks. This location is in a cut formed by blow sand and we have found no method of stopping or preventing it. We simply allow it to accumulate and every two years we use a caterpillar shovel and work train and load it out and dispose of it where we can along our tracks along fills. We take it out back to the right-of-way fence, about fifty feet from the track and down to a depth of about four feet below the grade.

"We have recently been experiencing trouble with sand on the track at various locations on the NT&SF between Perryton and Morse (Texas), which is caused from dry soil and high winds; the winds blow our right-of-way fence full of thistles and the soil drifts into these and drifts on and over to the rails. The only thing we have tried to do at such locations is to clean out the thistles from the fence as fast as possible and permit the sand or dirt to blow over and away from our tracks.

"My idea is, that if we can get a smooth hard surface, for 8 or 10 feet on each side of the track and in the roadbed between the ties and the rails, possibly with oil by placing sufficient to form a crust, it might permit the sand to blow away as it would not get a start to form a drift, also the sand in the immediate vicinity might be held by applying a heavy coat of waste oil to the right-of-way fence on the side where the wind prevails and which causes the blow.

Willow Mats in Highway Cut, Waynoka, Okla.

"The highway people at Waynoka, Oklahoma, have placed woven willow mats on the face of sand cuts along the paved highway south of Waynoka.

"The matting as shown, I think, is effective for location where placed on north and south highway and was placed to prevent blowing out of sand from sides of the cuts as it seems to be doing its work very effectively."

From R. C. Kline, Division Engineer, A. T. & S. F. Railway, Winslow, Arizona:

"Due to the dry season this year and the over grazing on the range at various locations, there is very little vegetation. As a result we have been troubled with blow sand at a number of new locations on this Division. In this country a wet spring starting the vegetation before April, materially reduces our drifting sand trouble."

#### **"Methods of Protection Against Drifting Sand—Albuquerque Division—The Atchison, Topeka and Santa Fe Ry.**

"The Santa Fe Railway, as located between Albuquerque and Winslow, crosses open sand flats and follows the San Jose and Rio Puerco Rivers for about 222 miles and is located on the banks of the Little Colorado, a distance of 30 miles between Holbrook and Winslow.

"The sand flats and streams are dry for about nine months in each year which exposes the dry sand which is picked up by the heavy southwest winds prevalent during the months of April, May and June.

"Many attempts were made to obtain protection from the drifting sand, none of which have been entirely effective.

#### **"Sand Fences**

"About twenty years ago a number of sand fences were constructed somewhat similar to snow fences. These failed for the following reasons:

"If the sand fence was constructed close enough to the track to prevent sand blowing across the rails, the sand soon filled up behind the fences forming a sand dune which gradually worked over towards the tracks. After the sand dune had reached the tracks, it was necessary in order to afford protection, to haul away all the sand that had accumulated behind the fences which entailed considerable expense. The tops of all these old fences have been worn away due to the action of the wind blown sand. If the sand fence is located a sufficient distance away from the track to prevent formation of dangerous sand dunes, they are too far away to prevent sand from blowing across the rails.

"As shown by photograph, where we have installed some old tie fences, you will note the accumulation of adobe and sand behind the fence. This layout, however, does not prevent the sand and adobe from accumulating between the rails on the main line. This fence is located about three miles west of Suwanee.

"At a location where we have trouble with sand just east of the Colorado River Bridge about three miles east of Winslow, an old tie sand fence was originally constructed near the right-of-way line, approximately 80 feet out from the track. After five years, sand had accumulated from this fence to the track, creating a dangerous condition which made it impossible to keep the top of the rail clear of sand during the heavy wind storms and it was necessary to move the sand accumulation with teams at considerable expense. The accumulated sand was removed to a point below the top of tie and in this way no obstruction was offered to the wind and the sand simply blows across each track, accumulates on each side of the rail, but not sufficient to cover the top of the rail. This is much less dangerous than the previous condition with the use of a sand fence. Wherever possible we have adopted this method of eliminating any obstructions above the top of rail and allow the sand to drift across the tracks, as we found that the sand does not accumulate over the top of rail with this method and as long as there is no sand on the top of rail, there is very little chance of derailment.

### "Planting Trees and Shrubs

"At a location about three miles west of Joseph City where the bed of the Little Colorado is exposed adjacent to the track, the river bed being about one-quarter of a mile wide at this point, the wind blown sand was very bad. The sand trouble was practically cured for the time being by planting of cottonwood trees, shrubs, etc., which prevented the wind from picking up the sand in the river bed. We found, however, it was necessary in this free range country, to build a fence out into the river to prevent cattle, burros, horses, etc., from eating tender leaves on the young plants and trees. This method is effective but not permanent. The first time the high water in the river flows through this territory, the young trees, shrubbery and our fence will be washed away in a few minutes. The shrubbery, etc., has afforded us protection for the past two years.

"In the LeRoux Wash located about three miles west of Holbrook, the blow sand accumulates against the south side of the girders. The sand does not accumulate on the lee side of the bridge. The sand had accumulated as high as the deck timbers, entirely filling the two easterly spans and a portion of the third span of this bridge. The sand was cleaned away from the girders of this bridge with a ditcher and ten days after the work was done, the sand was as high as it was before the ditcher was used.

"The sand that we are troubled with on this Division is a very light grain blow sand which is easily washed away by the first high water."

From C. H. Purcell, State Highway Engineer of California, by T. H. Dennis, Maintenance Engineer:

"As to our experience with drifting sand:

"We have had considerable experience along this line in the Mojave and Colorado Deserts in the southeastern part of the State and in connection with sand dunes along the sea coast in the northwestern part.

"Control measures in the desert sections consist of the following:

1. Establishing the grade line of the roadway at an elevation such that the wind action will keep the paved surface free from sand.
2. Oil shoulders and slopes.
3. Cut channels through sand dunes at locations designed to retard and check the forward movement of the dunes.
4. Erect fence on the order of the lath type snow fence to catch drifting sand before it reaches the roadway.

"On the Coast section, the only control measure has been the planting of coarse species of grass and plants to retard the movement of the dunes.

"Item 1 is self-explanatory. The grade to be established is determined by observation of local conditions.

"The oil used under Item 2 was so-called light fuel oil having an asphaltic content of 40-50, or 50-60% of 80 degree penetration asphalt. The rate of application varied with the conditions, from  $\frac{1}{2}$  gallon per square yard of area treated to one gallon per square yard. The lighter oil gave good penetration without heating. The heavier oil must be heated to about 175 degrees F. before applying.

"The channel type of work referred to in Item 3 applies to locations where the dune encroaches in the shape of fingers. By cutting channels parallel to the roadway across these fingers, space is provided for the drifting sand and the movement is retarded thereby. The space between the fingers of the dune provides storage for sand removed from the channels. The frequency of clearing the channels depends on conditions."

From J. W. Williams, Chief Engineer of the Western Pacific Railroad:

"The Western Pacific is employing three methods of protection against drifting sand, the protection used being governed by local conditions, physical and climatical, and can be classified under the headings of 1. Sand Fences; 2. Trenches; 3. Vegetation.

"1. SAND FENCES:

"(a) Lath Fence—In 1929 the Western Pacific put up one and one-half miles of sand fence in the vicinity of Bronte, Nevada, on the Smoke Creek Desert where drifting sand has given considerable trouble. The fencing material consists of 4 ft. lath, spaced  $2\frac{1}{2}$ " apart, and held in that position by five double strands of #15 gage galvanized wire and comes in 5-rod rolls of continuous fencing. The fencing was attached to old ties removed from track after tie renewals. The cost of this fencing was 10¢ per linear foot of fence. This type of fence is giving satisfactory service and since the installation the track at this point has been free from sand.

"The Los Angeles and Salt Lake Railroad has had considerable experience with the use of this type of fence, installing same in single, double and triple lines, depending on conditions, and in some places, it has been found necessary to extend the fence higher by adding a complete section.

"(b) Snake Fence.—In 1932 sand fences were put up with old ties in the form of an old-fashioned snake fence, without being fastened together. These ties were obtained from tie renewals in the immediate vicinity of the fence job. This type of fence, although no costs are available, is very much cheaper than the lath fence described above. This fence has not been in sufficient use to permit of an opinion as to its effectiveness.

"2. TRENCHES:

"In 1930 the Western Pacific dug trenches as an experiment for protection work against sand being blown in the track between Salduro and Arinosa, Utah, on the Great Salt Lake Desert. Three trenches 3,000 feet long were dug parallel to the track, spaced 96 feet, 83 feet and 67 feet, respectively, from the track. At intervals of about 700 feet cross trenches were dug at right angles to the track and extending between the two outside trenches. These trenches were 24 inches wide, 30 inches deep, and can be constructed at a cost of 2¢ per linear foot of trench, under ordinary conditions of work.

"These trenches have not been in use for a sufficient length of time to definitely determine their worth. From observation, all the sand carried by small sand storms has been stopped by the first trench at the greatest distance from the track.

"This idea of trench construction as a protection was conceived from the experience of this and other roads in the manner of handling sand piled up at sand fences and other barriers. As the sand piled too high and too near the track roadbed it has been necessary to remove the sand by steam shovel or ditcher and during this operation a trench was generally dug to be later filled by the drifting sand stopped by the fence barrier. In the trench system, as employed by this road, it is the conception that the trenches will serve as a barrier and depository to the drifting sand, thus obviating the necessity of fence construction.

"3. VEGETATION:

"The Western Pacific has recently planted a vegetation called 'Sea Bent Grass' on the slopes of some of its sand cuts in Nevada and Utah. This grass has been furnished by the Superintendent of Parks, San Francisco, Calif. It has been extensively used around San Francisco where hundreds of acres of sand wastes have been reclaimed with it. This grass has also been shipped to Michigan and north European countries and has done well in all instances, proving its resistance to cold climates.

"The Southern Pacific has used the Sea Bent Grass extensively near San Luis Obispo with success.

"As this Sea Bent Grass has been planted this year, there is no definite information that can be given at this time as to results obtained on our line.

"The Western Pacific, in its experimentation, is endeavoring to solve its sand drifting protection according to the local problems involved. Our problems are such that no great drifts have accumulated where fences have been used and for our particular problems fences of the type described under 1 (a) above have proven satisfactory and of

more than as a temporary barrier which would be the case where great quantities of drifting sands occur. We are very much interested in the success of the use of the Sea Bent Grass as a protection to drifting sands and believe that its extensive use can solve many problems, especially the drifting of sand in cuts."

From Division Engineer A. B. Truman, of the New Mexico Division, Santa Fe Railway:

"We have had more trouble all over the division this year on account of sand drifting on to the track than at any time during the past ten years. Between Levy and Wagon Mound we have a cut about six feet deep and 500 feet long which I believe would have drifted full had we not extended every effort possible in keeping this clean by use of the American ditcher and all of the men available in that territory.

"Just east of Deming we have experienced more or less trouble account of sand drifting on the track, but three years ago the right-of-way was entirely cleared of all the mesquite brush which had grown up on the right-of-way and the leaving of the ground clean and without any obstruction has almost entirely overcome the trouble at this point.

"We have not put up any sand fences or other obstructions in an attempt to prevent sand from drifting on the track, as in most cases our right-of-way is too narrow to permit of any arrangement of this nature."

From R. H. Baldock, State Highway Engineer of Oregon:

"We have had considerable experience with the control of blow sand along the Columbia River since 1920, by oiling and have found it a most successful way to overcome the raveling of slopes and the movement of dunes.

"Our experience indicates that a light grade fuel oil, having an asphaltic content of not over 50% with a viscosity below 35 (Saybolt Furol at 122 degrees F.) should be used. It should be applied at the rate of 0.12 to 0.20 gals. per sq. yd. In the Spring of 1933 we oiled 219,600 sq. yds. of sand slopes with an oil of about 55% asphaltic content. This oil was applied at the rate of 0.14 gals. per sq. yd. at a cost of \$0.0099 per sq. yd.; divided as follows:

|                                              |            |
|----------------------------------------------|------------|
| Cost of 30,410 gals. incl. freight .....     | \$1,255.93 |
| Cost of Sealing .....                        | 143.12     |
| Cost of Applying (Incl. rent of eqpt.) ..... | 775.87     |
|                                              | <hr/>      |
|                                              | \$2,174.92 |

"The equipment used consisted of a steam boiler to heat the oil, an ordinary pressure road distributor, equipped with hose 300 ft. of 2½ inch old fire hose having a fan shaped nozzle, a small truck and ladder for climbing cut banks. The oil was heated to 175 degrees F.

"It is not desirable to apply too heavy a coating of oil as the principal advantage of oiling is that it enables weeds and grass to start in the cracks of the crust so that in many instances a dune is completely restrained by natural vegetation within a few years. It is preferable to oil early in the spring or soon after a rain while the sand is firm and not moving. The moisture is also retained to germinate seeds of any grass or weeds present. The number of re-oilings and intervals between is quite variable, depending upon how quickly vegetation can be induced to grow and whether the sand is blown in from distant sources. Stock should not be allowed to run at large over oiled spots as they soon destroy the entire crust. We have in some instances been compelled to purchase additional right-of-way so as to fence out the stock from the oiled dunes. In general it is desirable to go over the sand ground about the first or second year to re-cover the spots that were poorly oiled. In most instances this has effected a semi-permanent cure by the growth of vegetation so that we have had no further re-oilings in eight or nine years. In one place on the Columbia Highway near Dillon a large moving dune has entirely disappeared due to oiling the area which supplied the dune, so that we have been able to improve the alinement where it was originally thought necessary to by pass around the dune.

"In the coastal regions along the Coast Highway, where oiling is objectionable from aesthetic viewpoint, we have made extensive plantings of Holland grass, Huckleberry and Scotch Broom, principally on high cut slopes. The transplanted vegetation has grown fairly well, particularly the Scotch Broom, but the method is rather expensive and its

success rather hard to predict on individual cuts. Sand cuts should have a slope of from  $1\frac{1}{2}$  to 1 to 2 to 1 even in areas of heavy rainfall to prevent the sand displacing around the plants. Some protection can be given by windrows of brush along the slopes."

From R. C. Gowdy, Chief Engineer, Colorado and Southern Railway:

"Both the Colorado & Southern and the Fort Worth & Denver City lines, the latter being the Texas line of the system, were troubled with drifting sand to an unusual degree all last winter and spring due, I think, to two principal causes—

1. An unprecedented amount of wind storms of high velocity and duration.
2. The large amount of sod land which had been turned over and on which no crops had been planted because of the drought and winds.

"On both the Colorado & Southern and the Fort Worth & Denver City there were considerable areas of sandy territory which have always given some trouble, but I think the greater part of the trouble which we have experienced this year came from land which had either been plowed or which had been cultivated in former years and subsequently abandoned. On the Colorado & Southern trouble was experienced in spots over practically the entire length of its main line mileage from Wendover, Wyoming, to Texline, Texas, the worst place being at Sandy on the double track line between Pueblo and Walsenburg. At this point the line is in a cut some 3000 ft. in length, and constant work with ditchers, spreaders and hand labor was required to keep the line in operation. At times the southbound track was completely covered, making it necessary to abandon temporarily operation over that track. Conditions at other points were not as bad as they were at Sandy, but in places we had a great deal of trouble, requiring constant patrolling of the track.

"On the Fort Worth & Denver City the trouble was confined largely to the main line between Amarillo and Texline, and to the branch line recently constructed between Childress and Pampa. On the main line the greater part of the trouble was caused by sand and soil from newly plowed or abandoned fields, and we had a good deal of the same trouble on the Childress-Pampa line, but certain parts of the latter line are located in sandy country in which we had a great deal of trouble.

"The risks resulting from drifting sands are exceedingly serious and we had on the Colorado & Southern and Fort Worth & Denver City several derailments of freight and passenger trains as a direct result, and on the branch line between Childress and Pampa, a motor car was derailed and turned over. Sand would accumulate over the rail in a few moments to such an extent that the passage of a train was exceedingly hazardous, and it was necessary to operate trains at slow speeds in territories where trouble was anticipated. As long as sand kept moving we had no trouble with it, but drifts would start from the most trivial causes, such as shrubs, poles and even tin cans. On the Colorado & Southern we had a very considerable amount of trouble due to small windrows left on the tops of light fills several years ago when a Jordan spreader was operated. Sand drifting just above the surface of the ground was obstructed by these windrows and piled up in the cut ditches and over and between the rails.

"Except on the branch line between Childress and Pampa where permanent sand fences were built when the road was constructed, we had no protection and depended largely on temporary fences built of grain doors, ties piled rail fence fashion, etc. On the Colorado & Southern considerable relief was afforded north of Denver by the use of gunny sacks wired to the right-of-way fence, which of course, made the property look exactly like the "widow woman's farm".

"Sand is being removed by means of ditching machines, clam shells, spreaders, teams, and to a limited extent, by hand. This work is now in progress and what the cost will be I am unable to state, but it will undoubtedly run into thousands of dollars. Miles of cut ditches were entirely filled up, and many culverts were either blown entirely full or their ends entirely covered. This latter situation was particularly serious on the lines of the Colorado & Southern north of Denver where we have hundreds of boxes and culverts carrying irrigation water.

"I am not prepared to make any recommendations as to methods of curing trouble of this kind, because I think that each location should have individual study. In some cases, fences parallel with the tracks will do the work, while in other cases, spur fences at an angle to the track are better, and in both methods, the distance which fences should be placed away from the tracks must be considered. As a general rule, I think that the best relief which can be gotten is to ditch cuts as wide as possible with the bottoms of the ditches 3 or 4 or even 5 feet below sub-grade, and with the sides of the

cuts given as flat a slope as possible. In other words, having the track on a fill in a cut. This method has proved effective with drifting snow and wherever we tried it with sand, it has also been effective. It has, however, the disadvantage of being an expensive method. Oiling on either side of the tracks has been tried and found to be reasonably effective, but such large areas were involved last winter and spring as to make that method impossible and impracticable."

Fort Worth and Denver City—Drift caused by tumble weeds on fence.  
Some sand in track.—Texas.

Colorado and Southern—Sand fences and drifts—Colorado.

From Paul Chipman, Pere Marquette Railway:

"The Pere Marquette has but a few locations where trouble is experienced from drifting sand. The worst of these is south of St. Joseph, where the right-of-way is adjacent to a narrow strip of beach. Although the tracks are 40 to 50 ft. above the beach, much trouble was experienced in the past from sand accumulating on them. Fresh sand would be deposited on the beach after each storm, which would dry out and be blown up the slope, over the shoulder and on to the tracks. A fence with tight horizontal boards was built near the top of the slope for a portion of the distance and

has proved effective. On the remainder of the distance affected, a loose crib of old ties was built near the top of the slope, its top being about 2 ft. above the track level. This was not so effective, as sand blew through the openings and part of it finally got on the track. Further, it was undermined in places by people who would cross the tracks and go down the slope to reach the beach.

"This trouble could probably be avoided by planting willows at the foot of the slope, but this is off the right-of-way and the owners of the beach are very jealous of their rights. It is hard to get willows started on the slope owing to the looseness and dryness of the sand and to its frequent disturbance by trespassers.

"At other places we have used a tight fence of old ties set on end, which has proven effective."

From Mr. Eckert of the State of Michigan, Highway Department:

"We use, for this work, cuttings of Weeping Willow (*Salix babylonica*) and Lombardi Poplar (*Populus nigra*). These cuttings were made in the early spring, and were planted as soon as the frost had entirely left the ground. The results that we obtained were entirely satisfactory, the Willow making an exceptionally large growth. I would recommend this method of handling in planting work, and would endorse the use of the two above named varieties of plant."

From E. R. Lewis, Michigan Central:

"At Michigan City, the Northern Indiana Public Service Co. made a lawn and driveways and erected buildings on the sand dune site after leveling the dune, in which excavating they dug up three lines of fence we had placed at successive elevations. Sand fence not only is a temporary measure, but it tends to collect and heighten the sand and so make the matter worse.

"The only effective remedy I know is to get some grass or vine started which will spread and hold the sand from drifting. It is advisable to explore the immediate neighborhood and select if possible a perennial low growing, quick spreading plant for this use.

"In 1914 the structure carrying the DSS&A Ry. track over the track of the CStPM&O near Rockmont, Wisconsin, was replaced, involving a considerable lift in the approach embankments which was made with fine sand from Lake Nebagamon. The sand fill extended for about 3000 feet on the East and a somewhat less distance on the West. Horse tail probably grew in the sand pit and was picked up by the steam shovel. Without other planting, it half covered one slope during the first year. At the end of the second year both slopes were completely covered. Horse tail, *equisetum equisetaceae*, is a six inch joint grass which is indigenous to our eastern, western and northwestern states. Its roots spread horizontally, and with great rapidity yet they are astonishingly strong and fibrous, throwing out new plants at intervals of a few inches. The wide branching fine joint grass is the sterile plant. The fertile plant is a single thicker jointed stem without branches but bearing a terminal close fertile head. Horse tail is non-flowering, thrives in sand, cinders and otherwise bare soil. Sweet clover, wild morning glory, wild sweet pea and various other plants are of some value for slope planting. The problem is to get vegetation started before the drifting sand chokes it. I think sufficient shelter can be found about almost any sand dune to start vegetation and I would expect *equisetum* to grow anywhere in the Central States. I believe there are cases where it has been found necessary to build sheds over the tracks on account of drifting sand."

J. E. Willoughby, Chief Engineer of the Atlantic Coast Line Railroad, advises that on the A.C.L. there has been some trouble experienced due to sand ballast blowing away on the line between Haines City and Sebring, Florida, which traverses a ridge of sandy hills. The embankments of sand and the cuts through sand were the location of some trouble due to sand drifting almost to the top of the rail on one side of the track, while on the other side the sand ballast would scour from around the head of the tie leaving the end of the tie free. It was also found that on sand embankments the sand shoulder on one side would be almost entirely blown away with a corresponding accumulation of sand on the opposite side. This threat to the safety of the track was partly relieved by planting Bermuda grass along the slopes of the fills and in the track,

but it was not until the A.C.L. replaced the sand ballast with crushed stone and placed on the slopes of the fills a material containing clay that the difficulty was overcome. Since the beginning of the mining of soft limestone in Florida for highway purposes, the A.C.L. has been able to procure from the mines along its lines the clay over-burden and by spreading this clay over-burden on the slopes of the sand fills a further stability has been obtained.

From L. W. Colby, Sectional Engineer of the Central Cordoba Railway, Argentine Republic, we have received the following article together with authorization for its use through the cooperation of its author, C. N. Williamson, Chief Engineer of the Buenos Aires Pacific Railway, an English Company of some 3,000 miles of broad gage track (5'-6"):

## SAND DUNES

### PRACTICAL METHOD OF DEALING WITH THEM

"Dunes or sand drifts, formed by wind action, are universal in their occurrence as they exist in nearly every country in the world.

"They have two origins which might be classified as maritime and mediterranean.

"We will treat in this short article with the latter kind as it is these that interest us most, being prevalent in the Pampa regions, and we refer more especially to those in the Southern part of the Provinces of Cordoba and San Luis, crossed by the Buenos Aires Pacific Railway.

"In these regions there are great dunes already formed, which, due to the considerable height to which they have attained (10 to 12 metres) have become fixed, the outer ones being covered with natural growth of vegetation and the inner ones, that remain bare, offering no menace.

"In these dunes of vast extent and whose formation possibly dates back for more than half a century, great lakes have formed due to the continuous action of the wind that has scoured all movable matter down to the impervious bottom.

"These, however, are not the dunes which particularly interest us, but those of more recent formation.

"Undoubtedly all sand dunes have their origin on some bare patch, however small, that has lacked vegetation, as happens in the vicinity of cattle troughs, road gates and cattle yards, and also in over-stocked paddocks.

"If immediate steps are not taken to cover the bare patches with grass, straw, weeds, etc., the wind begins to burrow into them, the sand scoured from the hollow advances and we have the dune in its first or creeping stage, so much feared for its rapidity of advance and its devastating effects upon vegetation.

"If not attacked and stabilized, in a very short time it will increase in height and arrive at the second stage with its humps and hollows well defined.

"It is practically impossible to establish hard and fast rules to be observed in fighting the dunes, and each must be treated according to its form, height, etc., but nevertheless, the following procedure may be recommended.

"The first and essential measure is to fence in the drift to avoid the entrance of stock.

"Low or creeping dunes of recent formation may, as a rule, be checked by the sowing of oats, or for preference, rye when opportune; if small ridges exist, by covering these with straw, weeds, grass or any other adequate material disposable. This procedure was adopted in the South of Cordoba and San Luis during the last drought we suffered, with the best results.

"With regard to dunes already formed, the planting of Cana de Castilla (*Arundo donax*) is very effective. The canes are increased and multiplied by means of their rhizomas, it being possible to divide each tuft into a great many parts. The most propitious time for this is the end of winter as the canes then sprout rapidly and do not require the attention that would be necessary to avoid uncovering if they were planted at the beginning of or during winter.

"This class of cane has decided advantages over other vegetable binders due to rapid growth, drought resistance, immunity from the attacks from the "bicho de cesto" (basket worm) and ants, and the fact that it is not favored by the locust. Its reproduction is so rapid that in two or three years from the time of planting extraction may be carried out without affecting the plantation in the least degree.

"The canes may be cut at two years of growth and among the many uses to which they can be put we may mention the following: Covering bare patches of camp, making fences for seed-beds and gardens, fowl houses, shelters for stock, etc.

"The cane roots weigh on an average 300 kilos per cubic metre, approximately 1000 kilos being required to plant an hectarea, lines 5 metres apart and 1 metre between plants. The planting is extremely simple and requires no special knowledge nor great care except to avoid the uncovering of the rhizomas during the first few months.

### Planting of Castilian Canes

"If the dune to be 'killed' is of small area it can be completely planted with the canes, the lines being 5 metres apart and the plants 1 metre apart on the lines, the direction of these being generally from S.E. to N.W., or perpendicular to the prevailing winds.

"Where the dunes are extensive and total planting is not feasible the following method may be adopted:

"First, plant five lines of canes completely round the dune and then, from S.E. to N.W. (approximately) every 250 or 300 metre plant 10 lines (5 metres apart).

"The first summer the dune will appear to leave something to be desired but during the second the luxurious growth will attain to a height of from 5 to 6 metres. It is at this point that the beneficial effects of the planting begin to be appreciable, the canes forming an admirable windscreen and the mounds of sand between the transverse rows begin to level up.

"We now arrive at that period when the definite killing of the dune should take place and this is done by sowing the unplanted spaces, 250 to 300 metres wide between the rows, with rye.

"In the low-lands or valleys this operation can be easily effected by means of the seed drill, it not being necessary to cover the sown area with grass, weeds, etc., but on the rising grounds it will be necessary to broadcast the seed and cover with grass, straw or the cut canes laid over and secured with stakes and wire.

"Given the slightest rainfall, the dune may be considered as killed, due to the protection afforded by the growing canes, real parapets that impede the scouring action of the wind.

"The dune, being now definitely conquered, might be used for forestry purposes which, while beautifying the region, would also in time lead to positive results, but it would not be prudent to utilize it for pasturage due to the instability of the underlying sand.

"In order that these plantations might be resistant they should be closely planted, and a convenient distance between trees would be that of not less than 2 to 2½ metres.

"The trees which, in these regions, have given the most satisfactory results are Italian, Californian and Canadian poplars, white acacia (*Robinia*), black acacia (*Gleditschia*) and also the ash (*Fraxinus Excelsior*) which is of rapid growth and possesses the advantage of immunity from the attacks of locusts.

"The alternative to using the conquered dunes for forestry purposes would be to sow down a mixture of rye and alfalfa which would be permanent, and could be cut and baled.

"These procedures have been tried by the Buenos Aires Pacific Railway on a live dune of 350 hectares in formation with hummocks from 7 to 8 metres in height. This dune is now completely dominated and carries more than 500,000 trees, principally those already mentioned, besides, to a smaller degree, pines, cypress, white cedar, etc.

"These trees, almost without exception, have been raised in the nursery on the same dune.

"In spite of the drought of last year and the serious invasion of locusts, the plantations are in perfect condition.

"During the last few years sand dunes have also been attacked by means of plantations of Italian poplars on the system of the Agricultural Engineer, Sr. A. Miroli. The system consists of the planting of scions or stakes specially prepared and placed at a distance of 1 metre from each other in all directions, 10,000 stakes to the hectarea.

"The results obtained have been excellent, and even though the initial cost and maintenance for the first few years may be high, it will be more than compensated by the sale of trees, say at 10 to 12 years from time of planting.

"Among the countless uses to which Italian poplar wood may be put are the following: Paper paste, packing cases, toys, office utensils, wooden matches, charcoal (carbon de Belloc), etc., etc."

From L. C. Frohman of the Florida East Coast:

"On the Florida East Coast Railway we do not have the problem of the control of drifting sands, though approximately 75% of our road mileage is on sand embankment, or through sand cuts. Fortunately Florida is in an area of heavy annual precipitation and where the growth of natural vegetation starts very quickly and continues at a very rapid rate. On green sand embankments, or in sand ballast where the natural growth has not yet started, some minor difficulty is experienced due to "blows"—but these are never very extensive, nor serious. Usually before a "blow" can attain any important proportions the sand is heavily saturated by rainfall and periods between rains are not normally very lengthy.

"Along the Atlantic Coast there is practically a continuous 'barrier' of sand dunes adjacent to the beach. The sand in these dunes is the ordinary beach sand of fine grains, which are well rounded by abrasion due to constant movement under the action of winds and water. Normally these dunes do not 'creep' due to the almost continuous saturated condition, or condition of light moisture, for as stated this is a territory of heavy rainfall which is well distributed throughout most of the year. It requires a very stiff wind to create any appreciable disturbance of the sands when damp, or when saturated. While we have practically constant breezes, they are not stiff and, therefore, the rapid natural growth of sea grass and other native growths quickly starts on the surface of the sand. While this does not entirely cover the entire surface, there is relatively little disturbance of the exposed patches due to wind action because of the generally moist condition.

"Occasionally an area of 'creeping' sand is found, though I have no explanation to offer for this action in the midst of stationary dunes of the same sands. A small area of the 'creeping' sands is found along the ocean shore highway about 20 miles north of St. Augustine and extending for some miles northwardly. I am attaching a series of photographic prints showing the conditions in this territory, where the State Road Department has made some attempt to control, or retard, the movement of the sands by the construction of sand fences, consisting of vertical pickets on wire strands. I am referring to this and sending this information merely as an example of the difficulty of attempting to control the movement of these sands by artificial barriers. It will be noted that, in locations where there is a heavy growth of palm trees, other trees and thick, dense underbrush, the 'creeping' sands have sifted through the vegetation and gradually engulfed these natural barriers, which in some locations are more than 25' high. At numerous spots along this territory the white sands of the engulfing dunes can be seen through the heavy growth of trees and brush. Where it has started nothing seems to stop it, as for some reason the natural surface growths of sea grass do not seem to progress, or spread, rapidly enough to prevent scour and wherever there is scour the sand is moving. It will be noted that the drift fences do not stop the sand. The sand drifted between the pickets and continued on the lee side of the fence. With a solid barrier it builds up against the barrier until it reaches the top and then proceeds to build beyond the barrier.

"I can offer no explanation for this action in the locations illustrated, as, under apparently identical conditions of sand and natural growth within a few miles of the locations illustrated, there is no movement of the dunes."

Florida East Coast—Dunes drifted up around trees to bottom of fronds. Highway in foreground. Note buried fence erected about 1930.

Dunes forming, fence almost buried, trees partially buried. Highway at this point has been covered and cleaned several times.

Dune has engulfed scrub vegetation and is beginning to engulf highway, despite drift fence.

Drifting sand plunging through heavy, tangled growth of trees and brush and engulfs all growth.

From R. H. Chapman, Chief Engineer of the State Railways of South Australia, we have received a copy of a law enacted in that state in 1923, which requires the owners of land from which sand blows as a result of its being "cleared, fallowed, burnt over, cultivated, or grazed, to protect against such blowing of sand by some of the following means as directed by the Minister—

- "(a) Plant such land with Marram or other grass or plants;
- "(b) Brush the land or cover the land with seaweed or other substance; or
- "(c) Do any other thing prescribed, or may do some or all of these things."

Mr. Chapman also sent the following information as to the practices of that country in the protection against drifting sand:

"The areas in which sand drift occurs in South Australia may be divided into 3 classes as follows:

- (A) Old established agricultural areas where the drift consists mainly of fallowed ground.
- (B) Mallee country i. e. sandy country which in its natural condition carries a short stunted scrub known as Mallee. The drift here is caused by the clearing of this scrub.
- (C) Salt bush country i. e. pastoral country where the rainfall is less than 10" per annum and where the drift is due to absence of natural vegetation.

"In areas belonging to class A drift has been checked in a number of ways—

- 1. Brush wood fences have been built. These are not an unqualified success as they soon become buried.
- 2. Planting of grasses such as Ice plant and Marrom grass.
- 3. Planting of bamboos.

"Of these the bamboos are the most successful and the best results have been obtained by planting 4 or 5 rows about 15 to 20 feet apart across the drift.

"In areas belonging to Class B the only successful method of dealing with drift has been to limit the amount of land cultivated by leaving strips of uncleared scrub or by prohibiting the cultivation of a boundary strip on each block. This prohibition is enforced by the Sand Drifts Act.

"In areas belonging to Class C it is impossible to stop the drift. All obstructions are removed from the path of the drift so as to allow it to pass over the line. For this purpose fences are removed and cuttings are battered back to a slope of 1 in 5. Of course in this class of country the cuttings are nearly always shallow and permit of this being done.

"Where the above methods are not successful we are compelled to use work trains or horses and scoops to keep the track clear. The authorities controlling the highways of this state also use the above methods."

From H. Duncombe Bindley, Chief Engineer of the Sudan Railways, British Sudan, East Africa:

"The notes will give you some idea of the extent to which we are troubled but I fear that positive results for prevention are meagre, to say the least of it. For one thing we are subject to winds from different directions and partly on this account have been chary about the adoption of structures resembling snow fences as one day's heavy wind from the opposite direction might easily wipe out any good done during months of slow attrition.

## SAND ON LINE

### SAND DUNES

"Drift Sand and Sand Dunes affect the railway in several ways. Drift sand accumulates on the track, in bridge openings and against houses and buildings. That on the track requires immediate removal to allow for the passage of trains. That in bridge openings requires removal just before and during the rainy season—from the middle of July to the end of September. That against houses and buildings requires removal annually or monthly according to the rate of accumulation.

"Sand Dunes, where they exist, are more troublesome to deal with as their movements are spasmodic, depending upon the frequency of wind storms or upon wind of a sufficient velocity to cause movement of the sand particles.

Both drift sand and sand dunes have been the subjects of correspondence and theories and experiments but the large construction programmes and discontinuity in District Officials during the last 10 years has resulted in a lack of definite results of any value from such experiments as have been carried out.

"Apart from clearances of sand from the track carried out by the section maintenance gangs there have been parties employed on Abu Hamed District for the removal of sand from houses and buildings and from places where the track is in cuttings, amounting to some £E350 per annum on an average.

"Between 1920 and 1927 considerable movement of the sand dunes occurred at times of strong wind storms and train delays were not uncommon. The length affected was divided into the following sections:—

- (a) Covered with sand with slightest wind.
- (b) Covered with sand with very strong or continuous wind.
- (c) Clear of sand.

"Sand clearing parties with telephone communication were and still are established at Kilometres 415 and 445.

"At the end of 1927 the patrol orders were revised to allow of more latitude in the despatch of trains under conditions of (1) wind of less than 4 hours duration and (2) wind of more than 4 hours duration.

"Following on an article in the Geographical Journal of September 1927 and to further previous experiments carried out on similar lines arrangements were made for the District Engineer, Atbara District, to carry out trials with the erection of a line of sleepers along the crest of a dune. As the sand was removed by wind action and the sleepers fell down, they were to be re-erected in the same troughs that formed. On another dune experiments were to be tried out with erecting sleepers rather closer together than in the first experiment so that the areas denuded round each sleeper should overlap. The sleepers were to be re-erected as they fell over.

"It was thought that dunes so treated might possibly only move forward to some other site, but that in order for them to reform it would appear that some obstruction, either obviously apparent or due to the formation of the ground, must be present.

"It was hoped that if the experiment proved so successful as to cause the entire removal of a dune the reason for its initial formation on the site might become evident.

"Unfortunately owing to the large amount of new works being carried out at that time and to several unavoidable changes of engineers on the district the experiments were never carried out to finality and no definite results were obtained.

"In July, 1929 the sand belt at Kilom 445 had increased and the patrol length on account of sand had to be extended to Kilom 438; also a new danger area had formed at Kilom 427 to 428 and an additional sand party had to be established there. The formation of these additional dunes close to the line was attributed to tufts of grass being allowed to grow up, and steps were taken to have all possible tufts adjacent to the line removed.

"In October of that year the dunes that had formed at Kilom 428 had disappeared and the sand party was disbanded. No further trouble has occurred at Kilom 428 nor between 438 and 444 since that year. The site of these dunes was inspected this year and only two small dunes were present between Kilom 427 and 428, and these were some little distance from the railway line.

"One of the dunes at Kilom 444 has moved some 50 to 60 feet towards the railway line this year under the influence of the South winds.

"There is no doubt though that during the last few years sand accumulation on the line has diminished considerably and now that construction work has drawn to a close on account of the world depression in trade it would appear to be an opportune time to consider very carefully the possibility of adopting some means of dealing with these dunes.

"As stated previously the results of experiments made in this country are meagre and it would appear that before we can come to any satisfactory solution of the problem of how to cope with the drift sand and sand dunes, and thereby eliminate the annual cost of sand clearing and patrolling parties, we shall have to carry out some extensive and varied trials of different methods.

"The sand problem confronts railway men in North and South America, Australia and Egypt but although some remedial measures have been adopted with varying success the whole problem is so largely dependent upon local conditions that it is only by trial and error that the most effective measures for any one country, or any one locality, can be discovered.

"Attached are copies and summaries of such information as I have been able to gather together on the subject of sand dunes and their treatment."

Enclosed with Mr. Bindley's letter were the following articles quoted from other authorities:

"W. S. Barclay writing in the *Geographical Journal* of January, 1917 describes the sand dunes of the Pampa del Sacramento in Peru.

"The general direction of the wind is from the northwest, being caused by radiation from the desert surface and the consequent inrush of cooler air from the Pacific. It blows at about 20 miles an hour, and the sand which it releases travels at about 2 miles an hour on the hard flat surface between the ridges. The wind starts as soon as the desert warms up and increases in violence with the rising temperature, attaining its maximum force between 2 p. m. and sunset.

"The dunes take a typical half-moon shape and proceed in sequence south-east across the Pampa until they reach some large obstacle or abrupt change of level. If the barrier is negotiable they adapt themselves to cross it, the dune projecting itself into the easiest passes and elongating up to the limit of its sand-mass. Once the obstacle is crossed, the vanguard of the dunes marks time until the rear catches up, forms once more into a half-moon shape and proceeds on its way. These dunes often attain a considerable size, measuring up to 50 yards between the points of the horns.

#### PEBBLE CURE:

"Platelayers and other railway men whose duties necessitate watching them state that the dunes rate of march is about 100 yards per annum. The dunes occasionally advance over or threaten the railway line and the method adopted of avoiding the threatened obstruction is simple but efficient.

"Men go out with long handled spades and a wheelbarrow and collect loose pebbles and grit from the surface of the Pampa. This they scatter in a tin layer over the back of the dune. The pebbles arrest the action of the ripples and so interfere with the even circulation of the sand particles, which is apparently as essential to the progress of the dune as the circulation of blood to a human being. Very shortly the dune assumes a lopsided shape, sagging where the debris has been cast upon it and offering, instead of a well rounded back, a breach to the action of the wind. The process of disintegration is fairly rapid, and at the end nothing is left on the Pampa except the original wheelbarrow loads of grit and pebbles. Generally speaking the smoother the surface of the Pampa and the higher the wind, the larger and more perfect becomes the dune."

#### EXTRACT FROM AN ARTICLE IN THE GEOGRAPHICAL JOURNAL OF SEPTEMBER, 1927

"Much has been written about eddies in connection with dune-formation. The only observations I have made in this connection have been when endeavoring to place temporary marks on dunes to form survey points; and the observation seem to show that if eddies are artificially created at the top of a dune, a rapid lowering of the dune-crest results. At first I used to thrust a walking stick or ranging rod some 2 or 3 feet into the dune-crest. The stick or rod, though quite firmly fixed at first, was always found after a few hours lying half way down the dune-slope. The same thing happened with tripods firmly pressed down into the crest. When I was carrying out a little triangulation to determine the position of Rohlf's cairn at Regenfeld in 1924, I had occasion to place a mark on a high dune, and I used an empty 4-gallon petrol tin filled with sand, bedding it well into the dune; but the next day it had disappeared from the crest, and was found, as the other things had been, halfway down the slope. These observations remind me of Mr. Barclay's description of the method of dealing with sand-accumulations in the Peruvian Desert, where, as soon as dunes appear and threaten to obstruct a railway, the local inhabitants turn out and scatter pebbles and stones on the dunes, and very soon the dunes are gone, having been carried away owing to eddies produced by the wind around the stones. This device for removing incipient dunes might, I think, be tried along the Kharga Railway, where the screens put up at Mr.

Harding-King's suggestion have not been entirely successful in preventing the encroachment of sand on the line. I am the more disposed to think an experiment of this kind might succeed, because I have noticed that at the gap in the Ramak Dunes (discovered by Col. Partridge and known during the war as "Partridge Gap"): there are great lumps, of silicified wood, which may have led to the gap being formed."

From the Railways in the Eastern part of the United States of America, several letters were received, but in all cases, the troubles from drifting sand were reported as of so little moment, that they can be taken care of by planting of vegetation or by fences.

From the Canadian Pacific Railway, reports were received, but the practices are confined to the erection of fences where trees cannot be grown, therefore, no copy of the reports is given here.

From Germany, the Committee received a letter from Dr. Buchholz who advised that so little sandy country exists there, that any drifting of sand is stopped by the planting of vegetation of some suitable sort.

From Russia, however, we received a letter and report, written by Professor Serge Kareischa, of considerable interest, which reads as follows:

"Methods of protection against drifting sand on the railroads of the Union of Soviet Republic.

"On the railroads of the Soviet Republic, only three roads are obliged to protect their lines from drifting sand. Such lines are—

"(1) The line from Krasnovodsk to Taschkent where the line passes through the desert, Cara Crum, on the length of 160 kilometers.

"(2) The Astrakham line of the Riason Ouralsk Railroad.

"(3) The line of the Transcaucasus railroad near Baku.

"For each line methods of protection against drifting sand must be different, according to the local conditions. During the construction of the Transkaspian line of the Central Asia Railroad, works on sandy sections (Cara Crum) were effected without paying attention to the action of drifting sands because the pernicious action of drifting sands was then unknown.

"The embankments and cuttings had the same cross-sections as on normal soils. The embankments having the width of 4.70 meters (15 ft. 5.0 inches) and the cuttings the width of 8.50 meters (27 feet, 10.6 inches). Very soon it was found that the slopes of embankments and cuttings were blown out by the wind and they were being destroyed. To prevent such results, the Maintenance of Way administration began to cover the slopes of embankments and cuttings with a layer of clay and to protect the tops of slopes by means of brush of Saksaul, a kind of tree growing in the sandy desert.

"Except for the blowing out of the slopes, the cuttings were very often fouled with sand blown in from one or the other side of the line.

"To protect cuttings from sand accumulations, they were widened to 9.6 meters (31 ft., 5.9 inches) and their slopes were made less steep.

"The information given above concerns sections where the sand is partly covered by Saksaul.

FIG. 1.

"Much more difficult is the protection against drifting sand in the form of moving hillocks called barchans. By the name of "Barchans" is meant moving hillocks of drift sands displaced from the sandy soil drifted upon the right-of-way and tracks of the railroad.

"The barchans form on the plan of a horse shoe (See Fig. 1) and dispose themselves parallel to the direction of the dominating winds. From the windward side, the slopes of the barchans are of devious pitches but they are steep on the opposite side.

"The movement of a barchan is that the rib a.b.c. moves forward with its steep sloping face. When the wind is strong, the barchans move forward quickly and the sand is moving in the air in clouds.

"When the barchans reach the roadway of the railroad, they continue their advance if they are higher than the formation, but if their height is the same as the height of the formation, the barchans stop and do not move further. Therefore, the top of the formation (the roadbed) must be higher than that of the barchans.

"By making the embankments higher than the barchans, they will be protected, or free from, the accumulation of sand upon them.

"The barchans are less pernicious for the cuttings if the cuts are broad, and the accumulations of sand are conveyed out by work trains. But the best way for protecting lines from drifting sand consists in creating of broad bands of plantations on both sides of a line.

"On the Central Asia Railroad, instructions as to methods of protection against drifting sands have been issued as follows:

"Instructions for the protection against drifting sands—

"(1) Great attention must be paid to the propagation and cultivation of plantations on the band of expropriation, particularly on sections with sandy soil or drifting sands.

"(2) In places where the track has been already troubled with sand drifts, if the track is not sufficiently protected with sand sheds, and where the roadbed is not high, and the soil is sandy, all plantations on both sides of the track must be abolished for the width of not less than 6 meters, and when the sand drifts very badly, for the width of 20 meters from the centerline of track.

"(3) The slopes of embankments and cuttings must be smooth and clean.

"(4) The gaps between the bottoms of the rails and the top of the ballast must be kept free so that the sand can pass without accumulating.

"(5) In clearing away the sand accumulations, the sand must be thrown from the track in the direction in which the prevailing winds blow.

"(6) In clearing away accumulated sand, care must be exercised to avoid the removal of the clay covering which has been placed to aid in the free movement of the sand.

"(7) The accumulation of sand heaps or other obstructions along the sides of the tracks must not be permitted because they help the formation of drifts on the track.

"(8) If the sand is brought to the line from a considerable distance, the formation of drifts at the distance of 15 to 20 meters from the track is advantageous because when such accumulations have reached a sufficient height, sand sheds may be based on their tops.

"(9) In places where the track is often deeply covered with drifted sand, ramparts must be formed at a distance of from 15 to 40 meters from the axis of the road. The height of such ramparts must not be higher than sand hillocks near the line. Generally, the height of the ramparts may be from 2 to 4 meters and rarely 6 meters.

"(10) Such ramparts can be constructed by placing along the line, dense sand sheds or sand enclosures of boards, branches of saksaul or cane.

"(11) Dense sheds or enclosures repulse the sand approaching them and to some extent cause it to drive along the sheds and partly to accumulate it on the side from which the wind is blowing.

"(12) Sheds and enclosures, not dense but with openings, do not repulse the sand well and do not cause it to be carried along the shed, but such sheds accumulate much sand until the drift becomes as high as the shed.

"(13) Dense sheds must be located not closer than from 20 to 30 meters from the centerline of the track or tracks depending upon the amount of sand which may accumulate. The end of the sheds nearest to the dominant winds may be turned toward the track to not closer than 16 meters from the centerline. The other end of the row must be turned from the track to 30 or 40 meters.

"(14) Sheds and enclosures not dense but with openings must be located not closer than 30 to 40 meters from the axis of the line and the ends must be turned to the track for a distance of not less than 20 meters at the windward end and from the track from 30 to 50 meters at the leeward end.

"(15) Before a rampart is formed of the necessary height for the protection of the line from sand accumulations, sheds and enclosures may be formed from most simple and cheap construction.

"(16) When a rampart of sufficient height to protect the track from drifting sand has accumulated along the line, dense sheds or enclosures for the protection of the track from sand and for deflections of sand along the rampart must be erected along the top. If dense sheds cannot be constructed, open sheds may be used but their effect will not be so good.

"(17) Before the dense sheds are completely filled with sand, they must be raised and reset on the top of the rampart (or drift) already accumulated.

"(18) If a shed is overthrown by the wind, it must be properly re-erected on top of the rampart.

"(19) When the top of the drift reaches the height of the shed, the shed must be placed further from the track.

"(20) If it is impossible to re-use the old shed, a new one must be erected at a greater distance from the track.

"(21) Where sand drifts badly, both slopes of the ramparts must not be covered with plantations. In such locations, the sheds should be so placed as to deflect the sand and accumulate drifts.

"(22) When the hillocks of dense sand are formed on both sides of the line, and their bases approach the roadway, dense sheds or enclosures must be erected on the tops of the hillocks.

"(23) If a sand drift approaches very near the roadway and continues to increase, a second row of sheds must be placed at a greater distance from the line.

"(24) For lines subject to the drifting of sand, a careful study should be made of all winds, both the dominating and secondary, as to their duration, force and directions in reference to the axis, or centerline, of the track.

"(25) The observations about winds must be made each day at the 7th, 13th and 21st hours."

"In 1912, the Russian Geographical Society established a scientific investigation station for studying the movement of drifting sand in the desert of Cara Crum on the Central Asia Railroad, Professor Doubinsky was appointed as director of this station.

"The observations of several years have indicated that the movements of drifting sands in the desert of Cara Crum proceed as indicated below.

"The drifting sands of the desert consist of moving rows of sand ramparts with gentle slopes on the windward side and steep slopes on the leeward side. By action of the wind, the sands from the non-steep slopes are moved onto the steep slopes, and in this way, the rampart moves gradually and extremely slowly, in the direction which the wind blows.

FIG. 2

FIG. 3

"One-half of the year, the winds are blowing in one direction and during the other half, they blow in the opposite direction, so the barchans change their form. That means that their bases rest nearly the same place, but their tops make a movement for half a year in one direction and the other half of the year in the other direction and their slopes change their steepness as indicated in Fig. 2."

"Thanks to this fact, the protection of the line from sand can be organized in such a manner that the ramparts (or drifts) can be made to leave the track in the valley between the adjacent drifts. After this is accomplished, the ramparts must be covered with plantation which will protect the line from further sand accumulations. (See Fig. 3)."

"On the Astrakhan line of the Riasan Ouralsk Railroad, experience has shown that the best way to protect against drifting sand is the setting along the line, at a distance of 40 meters, of rows of sheds firmly planted in the sand. If it becomes necessary to set several rows of sheds, the nearest to the track must be at least 10 meters distant. In places where sand ramparts existed along the line, the sheds were set on top of the ramparts. Cuttings when they are widened suffer less from sand accumulations than do the embankments. Even when the line is protected with sheds, sand, driven by the winds, from the slopes of embankments, form accumulations on the track.

"This evil was annulled by covering the slopes of embankments by plantations of local grass, *Ayropyrum arenarium*, also a *Kali*, and covering the slopes with branches of trees, brushwood, etc., often the slopes are covered flatly by snow sheds."

From J. M. Ashworth, Chief Engineer of the Victorian Railway of Australia:

#### SAND DRIFT IN MALLEE

"Prior to 1925 little trouble was caused by sand on the Mallee railway tracks. Since that date, however, the menace has steadily grown and, subject to seasonal modification, must continue to increase until general action is taken over the whole area of the Mallee.

"Inquiry has been made regarding methods and experiences of other Departments and the Government Meteorologist and the Curator of Botanical Gardens have been consulted.

"The State Rivers & Water Supply Commission, it is understood, are endeavoring to have a protective belt of scrub reserved along their channels and to have legislation enacted to prohibit summer fallowing within three (3) chains of their channel reserves.

"In 1923 an Act of Parliament was passed allowing the sale of reserves previously set aside to act as windbreaks in Mallee districts.

"Tracks now affected or likely to be in the near future are: Yaapect line, Panac line (portion only), Donald to Red Cliffs, Ouyen to Walpeup, Dumosa to Kulwin, Meatian to Manangatang, Swan Hill to Natya.

#### THE CHIEF CAUSES OF THE TROUBLE ARE:

- (a) The denudation of the natural scrub and vegetation account cultivation of the land and the subsequent disintegration of all vegetable binding matter in the soil.
- (b) The nature of the soil: The particles are very light, hence a relatively small wind velocity only is required to lift and hold them in suspension in the atmosphere.
- (c) The practice of Summer fallowing: This greatly aggravates the position.
- (d) The disappearance of the protective belt of scrub from side-widths of railway land.
- (e) Drought or succession of dry years rapidly increases the area finally denuded of protective vegetation. In wet seasons, except in the worst stretches, cropping or grass growth holds the sand in check.

"In dealing with the problem of protection of railway tracks against sand in the Mallee it is essential to remember that the trouble is not due primarily to the pushing or rolling of sand particles before the wind, but to the minute particles carried in suspension in the atmosphere.

"At a definite velocity (variable according to condition of surface) the sand is lifted and carried along by the air currents until such time as the velocity falls below the rate necessary to overcome the pull of gravity. The amount of sand carried in suspension per unit also depends on the strength of the wind.

"A fall in velocity occurs when part of the air current strikes an obstacle such as a fence, bush, or dead air pocket such as may be caused by a railway cutting, and sand is deposited, the quantity varying according to size, shape and height of obstacle.

"The sand is deposited on the *windward* side rising higher and higher till the obstacle is topped, then falling over till the normal angle of repose is reached. The height then goes on increasing and with no interference may in time ultimately form a hillock with the crest running parallel to direction of prevailing sand shifting winds.

"The effects at fences, cutting, and banks are shown in sketches below:

"The shallower the cutting the nearer to the track is sand deposited, hence in the earlier stages greater trouble is experienced with shallow than deep cuts.

"Sand piles up against bank on windward side with a long gradual slope against the wind. The leeward side of bank is clear.

## Preventive Methods Used

### (a) PRESERVATION OF SCRUB GROWING ON RAILWAY RESERVE

"The side width reservation is generally far too narrow to make a lasting and effective break. As time goes on the scrub is slowly overwhelmed from the fence line and finally the track is reached. The value of this belt is very great and its preservation as long as possible is essential.

In the past, the cutting and burning of the Mallee to protect Telegraph (mainly postal) lines has seriously lessened the life and effectiveness of the break. A notable instance is that of the Mildura line where trouble is being experienced at the points much earlier than it would have been in the ordinary course.

## (b) RESTORATION OF SCRUB BELT AND PLANTING OF AREAS NOT PREVIOUSLY COVERED

"Planting of various types of trees and shrubs (Blue-gums, Tamarisks, Peppers, Bamboos, etc.) has been done in several places without success. Most of the plants were overwhelmed by the sand or died; the few that survived have merely formed a fence over which the sand is building up.

"For practical purposes success in establishing plantations is only possible with large well grown plants put in big areas during a favorable winter so that the trees are well established and sufficiently large before the hot summer arrives.

"Shrubs such as Boolyalla, Wilga, etc., if raised in large quantities may be suitable, but it would be years before any appreciable quantity could be grown. The pepper-tree is also a possibility in view of its drought resisting qualities.

"Re-planting Mallee scrub is not practicable. Seedlings in quantity could probably be raised but their slow growth over a period of many years before they become of sufficient size to withstand the elements renders the proposition useless for dealing with large areas.

## (c) ERECTION OF SCRUB, HESSIAN, OR TIMBER FENCES

"These fences have been built at different distances from track and at various angles to same or prevailing wind.

"The straight parallel fence is the shortest and it is as effective as any other type. The fence should be away from the track and, subject to certain conditions, as close to boundary fence as possible.

"The function of the fence is to change the direction of the air current with its accompanying disturbance of wind velocities at a more favorable point than the normal one at top of cutting. The sand is deposited and tails out on the ground on top of the cut where it can be scooped clear as required. If no fence or scrub barrier exists the sand would be deposited at edge of cut and tail out down the bank. The shallower the cutting the nearer the top to track and the quicker rails are affected.

"Fences are only of use as protection for cuttings and their value there is in the deposit of the sand at a place where it can be scooped away at comparative leisure as against the constant attention and risk of derailment if allowed to run onto the track.

"For *banks*, fences are not only useless but a menace. Normally the sand piles up against bank on windward side. (see sketch No. 3 below) but should scrub or a fence project above the level of top of bank, conditions similar to those met with at a cutting are set up with attendant troubles.

"The object in dealing with banks should be to have a clear uninterrupted sweep of the wind. At many places removal of the scrub or fence is considered essential.

## (d) PLANTING OF MARRAM GRASS, MESEMBRYANTHEMUM (PIG FACE) etc. has been tried successfully to prevent drift (moving) sand, but is useless when dealing with conditions under consideration.

"In "Cassell's Railways of the World" is an interesting article dealing with the investigations of Engineers of the Union Pacific System with the question of the shifting sands of the Columbia River. Whilst their problem is not identical with ours, the results and protective measures adopted are in line with our own.

## REMOVAL OF ACCUMULATED SAND

The methods adopted by this Department are:—

"(a) Removal of sand by gang to allow passage of train, during or shortly after sand storm. This work is done against time and sand is shovelled to clear rails only.

"(b) Removal by tip trolley on rails or by tip wagon on trolley track alongside. This is done between times to ease position before next storm.

"(c) Scooping out of cuttings (horse drawn scoops). The work is chiefly done during winter months.

"(d) Plant train and special gang. This method is adopted for long cuttings where scoop lead would be too great.

## Remarks

"Although there are certain places where sand trouble will be experienced every year and such places are increasing and extending, in the majority of cases the points of attack

depend on the season, cropping and fallowing of the land. Protective action such as erection of fences, clearing the scrub, etc., should only be taken as occasion arises. The clearing of accumulated sand in cuttings or on lee side of fences should be done as often as necessary, but as far as practicable in the early Spring or Autumn.

"Consideration of the class of traffic also is important. The Mildura line with its night passenger trains demands greater precautions and expense than would be justified on other tracks with only an occasional Goods or Mixed train. Under existing conditions a storm will cover the rails within a few minutes.

"In most of the heavy sand country, cuttings are full, or mounds built up on top are ready to tail down after a few more storms. Where fences have been built with the idea of protecting banks or where there is scrub obstruction, the drift there also requires removal.

"Many thousands of cubic yards will require to be shifted and the task is, of course, impossible for the ordinary track force; on some of the lengths the gangs can do little else than keep the track clear for passage of trains and even that involves a large amount of time outside ordinary hours of duty.

"There have been many delays to traffic during present year and several derailments due to sand over rails.

"The prevailing sand shifting winds in the Mallee blow from the Western side of the line hence it is on that side that the main trouble is experienced.

"It is important that Road Foreman and Gangers should have a good knowledge of the underlying principles of defence. Each point requires to be dealt with according to actual conditions. A fence erected too high, or in wrong position, scrub cut incorrectly etc. may ultimately involve the Department in heavy expenditure.

## Recommendations

"(1) That where necessary all cuttings in question be cleaned out, and widened to facilitate the use of scoops; the Western side to be given preference.

"(2) That sand on the lee side of fences or mounds on the top of deeper cuttings be removed and top reduced in height where necessary, steps to be taken conjointly to cut out scrub or stumps to facilitate future work.

"(3) That scrub or brush fences and accumulated sand at banks be removed below drift line to top of bank.

"(4) That where directed brush fences be erected to protect the deeper cuttings where trouble threatens. Widening *short shallow* cuttings will probably be more economical.

"(5) That instructions be re-issued for the necessity of preservation of the natural scrub in the Mallee and that, except for cutting back to prevent fouling, no interference with the scrub for telegraph line purposes be allowed without instructions from Chief Engineer of Way and Works.

"(6) That where reserves or unalienated land adjoin railway lines, steps be taken to permanently retain a 10 chain belt outside fence line.

"(7) That this Department co-operate with other Departments and interested bodies with view to joint action and exchange of views."

From J. R. W. Davis, Great Northern Railway, with a report by one of his Roadmasters, G. G. Smart:

"Great Northern is troubled in a small way with sand, or sandy loam blowing into its tracks. River sand finding its way onto the track occurs chiefly in the valley on the Columbia, in the State of Washington.

"Sandy loam is troublesome in small areas in the Dakotas and Montana, and to a lesser extent in the State of Minnesota.

From Mr. Smart's report:

"The SP&S has considerable trouble with sand along the Lower Columbia, and they have done considerable oiling of the sand dunes, both on and off the right-of-way. It has been their experience where oil is used it should be of a heavy asphalt base, and should be heated before applying, and the surface of sand dunes given a heavy coating. This is fairly permanent, but has to be gone over occasionally, as if oiled surface is broken, wind will undermine it and start cutting. This is only practical where the area covered with sand is not too extensive.

"They figure that one gallon of oil will coat one square yard in good shape. The cost of applying varies as oil is sprayed on with pressure, a work train equipped with pump, tank cars and facilities for heating being necessary."

And now, having saved the most important until the last, we present a letter, with photographs, from Bernard Blum of the Northern Pacific Railway, in which he describes a type of fence which, instead of stopping and piling up the blowing sand, causes it to blow away, thus avoiding both the risks resulting from drifts and the cost of removing them.

"On some of our branch lines in Central Washington, we traverse sand country, where at times high winds prevail and sand storms are not uncommon. On account of the dryness of the country, vegetation is extremely light and the sand drifts in large quantities.

"Our Maintenance of Way people, through experience, have devised a sand fence which is most effective. I do not fully understand the principle involved, but I have observed it working during heavy winds and know it is very effective. I am attaching several photo prints as we have no standard plan to cover. The posts are cull piles which are driven by a pile driver and the side boards are placed at the top down for a distance of four to six feet, omitting any boards from the ground up for a like space. These fences are placed on the side of the track from which the prevailing winds come and are set about ten to twelve feet from the track. For some reason or other these fences cause a siphoning action and the wind strikes and is deflected down and blows through the open bottom of the fence at an accelerated speed, blowing the sand clear of the track.

Taken Near Casey on Walla Branch About  $10\frac{1}{2}$  Miles South of Pasco.

"In some country along our main line we have for some years oiled the slopes of sand cuts, using asphaltum base fuel oil. The oil is sprinkled by work train and the effect of the oil film is lasting so long as the film is not broken. At one place south of Pasco, where there was considerable trouble due to shifting sands, the Northern Pacific in conjunction with the Washington Highway Department sprinkled 180,000 gallons of fuel oil over the sand waste to prevent it blowing across the railroad right-of-way and state highway. The area covered was 72 acres. On the opposite side of this sand waste is located the OWRR&N Ry.

"In previous years the OW had similarly sprinkled the sand lying on the opposite side of their track and the oil film had proven so effective that the Highway Department decided to use the same scheme. The use of oil is expensive and is probably only justified in extreme cases.

"A different type of sand fence, somewhat along the design of portable snow fences, has been used along the SP&S Railway, a subsidiary of the Northern Pacific. The fences are placed in echelon. They serve the purpose well, but require considerable maintenance in raising the fences up as the sand accumulates."

From the information given above, it appears that the most common method of combating drifting sand is by the erection of fences similar to those used to protect against the drifting of snow. One important difference exists, however, between protecting against drifting snow and drifting sand. In the case of snow, it is only necessary to keep the drifts off the road during the winter and the warmer weather of spring removes it from further consideration, but the sand drift once deposited remains to be reckoned with. It is, therefore, evident that the desired remedy in the case of blowing sand is either to prevent its starting to blow or to prevent its drifting at places where it will cause trouble.

Shows Drift to Windward of Track and Fence. Note Guys Fastened to "Deadmen" in Sand to Prevent Fence from Blowing Over.

Two features of the latter plan that have been brought out in the information given above are deserving of further mention. The first is the open bottom sand fence, as described by Mr. Blum. This type of fence acts as a "wind chute", thus directing the force of the wind downward at the critical point, thereby increasing its intensity close to the ground, thus causing it to pick up and carry away the sand with which it comes in contact under such increased pressure. It is very probable that such a fence, built on an angle from the vertical with the top of the fence inclined in the direction from which the wind is blowing might make it even more effective than a fence built vertical.

The other feature is that suggested by others of keeping a railway track half skeletonized where drifting sand is to be contended with. This is in fact Mr. Blum's plan on a smaller scale.

### Conclusions

1. Protection against drifting sand, as is the case with snow, should begin with the construction of the road, be it Railway or Highway.

2. Wherever drifting or blowing sand is probable, the roadway should be constructed above the natural ground level where possible and all obstructions which might cause the deposit of sand should be removed and the embankments faced with clay, oiled sand or some other substance which will provide a smooth surface, thus allowing the blowing sand to keep on moving, thereby avoiding drifts.

3. If cuts cannot be avoided, they should be constructed with flat, smooth slopes and the drifting of the sand controlled by the construction of open-bottom wind chute fences as shown on page 400 of Volume 35 of the Proceedings.

4. On existing lines the same remedies should be used where applicable.

5. Wherever sand drifts occur between the rails of a railroad track, the ballast should be cleared out to a half skeletonized condition, to permit the wind to pass under the rails, thus clearing the sand away.

6. Where the source of the blowing sand can be controlled by the planting of vegetation, such treatment may be the most economical method of protection, and should be considered.

7. Where moving sand dunes exist they sometimes may be dissipated by the scattering of gravel or small stones over the face of the windward slope.

8. Where trouble is experienced from sand blowing out of embankments, thus undermining the track, or from its blowing out of the sides of cuts causing slides or other damage the proper remedy is usually the covering of such surfaces with a layer of clay or other stable material.

The Committee recommends that the above conclusions be adopted for inclusion in the Manual and that the rest of the report be accepted as information and the subject closed.

NOTE—An interesting paper on protection against drifting sand as practiced in Japan was received from Mr. S. Kurokuchi, Director, Bureau of Maintenance and Improvement, Japanese Government Railways, after the above report had been completed and ready for publication. This will be considered in a supplemental report next year.

## REPORT OF COMMITTEE XXIII—SHOPS AND LOCOMOTIVE TERMINALS

*Committee.*

*To the American Railway Engineering Association:*

Your Committee respectfully presents herewith report covering the following subjects:

- (4) Turntables (Appendix A.)
- (5) Power Plants (Appendix B.)
- (6) Wheel Removing Equipment for Engine Houses (Appendix C.)
- (8) Car Paint Shops (a) Freight, (b) Passenger (Appendix D.)

Progress is also reported on the following subjects:

(2) Welding Equipment Installations as Applied to Shops and Locomotive Terminals.

- (3) General Reclamation Plants, collaborating with Purchases and Stores Division.
- (7) Car Wheel Shops.

### Action Recommended

1. That the conclusion in report on Subject (4) Turntables in Appendix A be adopted for inclusion in the Manual.
2. That the reports in Appendix B and D be received as progress reports.
3. That the report in Appendix C be accepted as information.

Respectfully submitted,

THE COMMITTEE ON SHOPS AND LOCOMOTIVE TERMINALS,  
J. M. METCALF, *Chairman*.

### Appendix A

#### (4) TURNTABLES

L. P. Kimball, Chairman, Sub-Committee; C. E. Beveridge, A. S. Kent, L. H. Laffoley, W. S. McFetridge, B. M. Murdock, E. H. Roth.

The conclusions of the report of this Committee as presented to the 1933 convention were approved for inclusion in the Manual, with the exception of No. 3, which refers to the method of installation for power-operated turntables.

The original recommendation of the Committee indicated a preference for the installation of wiring to turntables in underground conduits. In order to determine the

practice generally employed by railroads in their turntable installations, questionnaire worded as follows was sent to all of the principal railroads.

1. How many turntables do you have operated by electric power?
2. How many of the above turntables have power wires brought in overhead?
3. How many underground?
4. Are your modern installations made with underground or overhead wires?
5. Please advise reason for use of underground or overhead method as preferred.

The replies to this questionnaire are tabulated and totaled below:

| <i>Railroad</i>           | <i>Total No.<br/>Electrically<br/>Operated<br/>Turntables</i> | <i>Turntables<br/>With Power<br/>Connections<br/>Overhead</i> | <i>Turntables<br/>With Power<br/>Connections<br/>Underground</i> | <i>Preference</i> |

Of the 58 roads reporting eight (8) expressed a preference for underground connections; with forty-eight (48) reporting a preference for overhead connections and two (2) roads non-committal. The eight roads preferring underground connections have a total of 123 electrically-operated turntables, of which 71 have underground connections actually installed.

Reasons for preference of overhead or underground connections were fairly uniform; those in favor of overhead connections stating that their preference was on account of cheaper installation cost, ease of maintenance and greater accessibility and the avoidance of trouble which might be caused on account of interruption of drainage from turntable pits.

Those preferring underground connections state they consider that such connections will have less maintenance if properly installed; that the question of clearance is eliminated; that there is no deterioration of contactor supports and wiring from smoke and gases; that the underground connection eliminates the possibility of table being put out of service due to damage by fire or storm.

In view of the results of questionnaire the Committee recommends the following text be used for Conclusion No. 3 in place of that recommended last year:

3. Where modern locomotives are to be turned, mechanical power for operating turntables should be provided. Where current is available, electricity is the most reliable means of operating a turntable. The power wires may be led to the table, either overhead or underground. In either type care should be taken to see that installation is made so as to minimize the danger of interruption in case of fire, storm, inadequate drainage or other emergency. Where electric power is not available, a compressed air motor may be used.

## Appendix B

### (5) POWER PLANTS

E. H. Roth, Chairman, Sub-Committee; B. Elkind, C. E. Harris, L. C. Hinsch, E. E. Kimball, H. C. Lorenz, H. W. Williams.

#### LOCATION

Power plants at railroad shops and locomotive terminals are usually located in the vicinity of the major terminal buildings, after having given consideration to the plant's economical construction and distribution system. Very often these systems are other than electrical in character, such as steam for firing of locomotives, heating buildings, air pressure, and water supply. A careful analysis of its environment is made, giving consideration to the construction cost, maintenance, operation, and future legal entanglements; having in mind the avoidance of annoyance to the surrounding neighborhood. The adequate and economical delivery of fuel, handling of ashes, abundant water supply, smell of oil, and smoke are considered. Fire risk is given careful investigation as to its surroundings, since a power plant is liable to as great danger from fire in adjacent buildings as within its own walls.

Like commercial power plants, railroad power stations are constructed to supply their products on instantaneous demand, and in maximum amount required for the entire terminal to be supplied.

Space for future extension should be anticipated, in such form that enlargements will not destroy first construction or cause expensive alterations.

#### SUBJECT ASSIGNMENT

This subject is a new one and as assigned to the Committee on Shops and Locomotive Terminals it has been interpreted to cover the present practices by representative railroads in power plant operation, maintenance and recommended capacity at important locations.

Accordingly, a questionnaire covering the above features was submitted to various railroads, to which thirteen replies were received. The data therefrom has been assembled, which is as follows:

#### PLANT SIZES

The size of power plants averages 11,530 sq. ft., or about 90 ft.  $\times$  128 ft., the largest being 91 ft.  $\times$  244 ft. and the smallest 58 ft.  $\times$  97 ft.; neither of these two extreme sizes is equipped with electric generator sets. The rated boiler horse power per plant averages 2120, the maximum 6800, minimum 600. The maximum horse power plant reported is used for generating steam for the operation of compressors, water supply pumps (for fire fighting purposes only), and generation of steam for heating purposes. The facilities heated include the roundhouse, locomotive shops, office buildings, store houses, oil tanks, and the numerous shop buildings, located at an important locomotive terminal. The electricity used at this terminal is purchased from a public utility. Steam generated for heating purposes during winter months amounts to about 50 per cent of the total boiler capacity, 25 per cent for the operation of compressors, and the remaining 25 per cent being used as a reserve, or possibility of operating pumps for fire fighting purposes.

The smallest plant generates steam for heating purposes, which includes roundhouse, shop buildings, car shops, oil tanks, office buildings, store houses, and locomotive shops. This plant also is located at an important locomotive terminal, where all water and electric current are purchased from public utilities. The air compressors are electrically operated. About 50 per cent of the steam generated during the winter months is used for heating.

The larger plant uses coal for fuel, while the latter uses commercial fuel oil.

### FUEL

The fuels used are coal of various grades, and oil, depending on location. In all cases except two, stokers are used for coal fuel.

### GENERATOR SETS

Sixty per cent of the plants are equipped with electrical generator sets, and forty per cent purchase electric power.

### AIR COMPRESSORS

All plants are equipped with air compressor sets, operated either electrically or by steam, being on about 50-50 basis. Among those listed in the questionnaires, the largest compressor is of 5000 cubic feet capacity and the smallest 250 cubic feet. The average compressor capacity per power plant is 6020 cubic feet, the smallest 1500 cubic feet, and the largest total capacity per plant 11,000 cubic feet per minute.

### WATER SUPPLY PUMPS

Sixty-six per cent of the plants are equipped with water supply pumps, and thirty-four per cent either purchase water from public utilities or have separate pumping plants. In practically all cases drinking water is purchased. The pumps used are for general service and fire.

### STEAM HEATING

All of the plants reported on generate steam for heating purposes, supplying various kinds of heaters, such as—Hot Blast, Unit, Direct and Indirect radiation, including hot air distribution. The facilities heated include roundhouses, all classes of terminal shop buildings, oil tanks, coach yards, and office buildings, unit heaters, hot blast, and hot air distribution being generally confined to roundhouses and all shop buildings, while direct and indirect radiation is used in office buildings, diverging somewhat in a few cases, depending considerably upon the local conditions.

### FACILITIES SERVED BY AIR COMPRESSORS

Compressed air is used in all shop and locomotive terminal buildings, including car repair yards, coach yards, freight yards, oil tanks and houses, scrap shops, pneumatic tube systems, and furnaces.

### LIGHTING SUPPLIED FROM POWER PLANT CURRENT

Current for illumination is purchased in 75 per cent of the cases reporting, the other 25 per cent manufacturing their own current. In the latter cases current is furnished for all buildings and yards or wherever needed in the terminal.

### STEAMING LOCOMOTIVES AFTER FIRES ARE DEAD

Only one case reported keeping locomotives under steam by the power plant, averaging ten engines per 24-hour day. Three railroads recommend this practice, one in event conditions and costs justify, six do not, and three are non-committal.

### PER CENT BOILER CAPACITY USED IN HEATING

The average boiler capacity used for heating purposes during the winter months for the reporting roads is 52 per cent, for the fall and spring months 27 per cent, and summer months about 1 per cent. The highest usage reported for winter is 80 per cent and the lowest 25 per cent, while for the fall and spring months the highest is 50 per cent and the lowest nothing.

### PER CENT BOILER CAPACITY FOR GENERATING ELECTRICITY

Only three railroads reported generating their own electricity for all requirements. These three roads report using an average of 35 per cent of the boiler capacity for winter months, 33 per cent for fall and spring months, and 42 per cent for summer months.

### PER CENT BOILER CAPACITY FOR COMPRESSORS

The steam operated compressors average 19.7 per cent of the boiler capacity for the eight railroads reporting on this item, the highest percentage being 50 and the lowest  $1\frac{1}{2}$ .

### USE OF SUPPLY PUMPS

Eight railroads report using power plant water supply pumps for fire fighting purposes, three do not, and two have not reported. Only two railroads report using their own facilities in supplying drinking water, the remainder purchase from public utilities. Eight railroads use their own facilities in supplying wash water, three do not, and two have not stated. Five report using their own facilities for supplying general lavatory use, six do not, and two have not stated. Seven report using their own facilities for watering locomotives, four do not, and two have not reported.

### PER CENT OF TOTAL WATER CONSUMPTION

The average percentage of total water consumption used for locomotives for those reporting is 59, for lavatory purposes 17, and for drinking water practically nothing.

### RELATIVE COST OF ELECTRIC CURRENT

Seven railroads report purchasing current cheaper than it can be made in their own power plants, three report to the contrary, and three have not determined.

Five recommend allowing space for generators in new power plants, two recommend against, and the remainder suggest making special studies.

### RECEIVING AND DISTRIBUTING SUB-STATIONS

Energy is received at the sub-stations where current is purchased at a high voltage and there stepped down to the local demands. In some cases the phases are also changed to meet welding requirements, operation of motors, etc.

## TRANSMITTING METHODS

Two general methods are used for transmitting current from power plants or substations, namely: overhead construction or underground conduit depending on distance and local conditions. Within buildings conduit system is in general use. For air and steam both the overhead and underground piping are used, also depending on local conditions.

## SUPPORTING STRUCTURES FOR OVERHEAD CONSTRUCTION

The recommendations for supporting structures on overhead construction are fabricated steel towers and expanded metal parts, outside of roundhouse territory, and treated wooden poles within engine territory.

## Appendix C

### (6) WHEEL-REMOVING EQUIPMENT FOR ENGINE HOUSES

A. T. Hawk, Chairman, Sub-Committee; W. H. Barton, C. E. Beveridge, H. G. Dalton, A. G. Dorland, E. A. Dougherty, L. K. Sillcox, H. W. Williams.

### THE EVOLUTION OF DROP PIT EQUIPMENT

In the early days of railroading locomotives were raised by the use of jacks and blocking for the removal of wheels. Because of low roofs, the roundhouse work could not usually be performed in this manner, and the drop pit for the dropping of single pairs of drivers came into general use. At first, this was very crude—simply a pit in which blocking was placed on which stood a jack equipped with a “V” block to engage the center portion of the wheel’s axle. The wheels were lowered to a cart resting on the floor of the pit, then were moved sidewise, raised and released.

Two girders equipped with rails on top were used to bridge the drop pit. After the wheels to be changed were jacked high enough to clear these girder rails, the girders were removed from their positions on tops of the side pit walls. First, this change was made by hand. Later, a jib crane equipped with a chain block removed and applied the girders. Later, the girders were hinged at one end, making it possible to swing them into “clear” against the side walls of the drop pit. Even this method resulted in a good deal of manual labor because of their weight.

Later, a track was placed at the bottom of the pit on which ran a flanged wheeled truck that supported a large cylinder, piston equipped. Water or air under pressure served as power. Because of the weight of driving wheels, making a large cylinder necessary, pneumatic power soon had to be replaced by another power, especially as compressed air is exceedingly elastic, causing rapid changes in piston position when loads were imposed on the piston.

The cylinder portion had to be as long as the distance wheels were to be dropped. Dropping a pair of wheels six feet meant a pit 12' deep. To overcome this, the cylinder of the jack was held to the pit truck at its upper end, the lower end of the cylinder extending a considerable distance below the truck to reduce the depth of the pit, requiring a deep bottom center slot parallel with the pit’s side. The slot, because of its narrowness and extreme depth, gave considerable trouble from water and other obstructions. It was difficult to regain tools, locomotive parts and blocks that had fallen into it.

To overcome these objections, the hydraulically-operated telescopic type jack was developed, allowing elimination of the pit slot.

While the jack and pit construction were evolving, the hydraulic equipment to the jack was being improved. At first, large jack cylinders were used to obtain the necessary plunger power provided by the plant water pressure. As weights increased, water pumps hand operated, later power operated, were used, the first ones being air operated. Steam and electricity for this additional power also have played their parts.

Counterbalanced wheels could not be dropped without the wheels turning unexpectedly on the "V" block in attempting to find a balanced position. Frequently, when lowering driving wheels, driving boxes became cramped on one side of the locomotive, causing only one wheel to lower. The mounted wheels slipped sidewise on the "V" block and sometimes fell into the pit. Drop pit jacks for dropping driving wheels, up to and including this stage of jack development, had caused many serious accidents.

As locomotives grew heavier, the running repairs increased. Extended locomotive runs made more wheel work necessary at important terminals and there was a demand for platform tops in connection with drop pit jacks in order to eliminate the hazards of dropping driving wheels by the axle center-support method.

Platform tops resting on a large flat surface at the end of the jack's plunger were a long step towards greater safety. These tops were equipped with rails in alignment with those on roundhouse pits served. Wheels being dropped rested on the platform top served by the jack. The platform tops are of the detachable type and are locked, in rail-level position, to the side walls of the drop pit, allowing the jack to serve other stalls and platform tops. These tops, of course, replaced the hinged girders, equipped with rails, that formerly were used to serve as a bridge over the drop pit.

Platform tops first were of such width across the drop pit as to only drop one pair of driving wheels. Later the width was increased so as to make possible the dropping of two pairs of small drivers or a complete engine or tender truck, and capacities of the jacks were increased to handle these additional loads.

At this period of the jack's evolution, the following objections made necessary a departure in the prevailing design:

1. With a plunger type jack, hydraulically operated, the load rested on a fluid under compression. It was found difficult to obtain positive positioning as the least leakage caused a slight drop of the load, and no check valves could be made absolutely air tight.
2. Many times it was necessary to raise loads greater than seventy-five tons with platform above track level position. Such loading had a tendency to distort and cramp the telescopic sleeves that made up the plunger.
3. The platform top, not attached, but only center-supported on the plunger of the jack, made necessary the center-loading of the weight to be lowered. Careful "spotting" was required and an unbalanced load presented a hazard.
4. The use of water under compression was objectionable, not alone because of its characteristics and the necessity for a clumsy flexible feed line in the pit, but because of the pumping mechanism of the power operated type on the jack truck. Automatic or safety features for this source of power were only obtained with difficulty. Flexible or remote control also could not readily be obtained. In fact, the stage was gradually being prepared for that modern and economical source of power, electricity, the power that was to overcome the objections found in the hydraulically-operated drop pit jack.

## Drop Tables

The four-screw electrically-operated drop pit table finally made its appearance. It overcame the objections found in hydraulically-operated drop pit jacks. It was self-locking and could be safely maintained in any position. Its capacity was such that it could handle many operations requiring the platform top above track level position, such as when changing tires or making repairs on spring rigging. Because of a lifting screw at each corner of its top, it could readily handle unbalanced loads, without danger or undue stresses on the table. By using electricity as a source of power, it was possible to safeguard operations through limit and control switches. Furthermore, remote control, through a pendant switch, made it unnecessary for the operator to enter the pit during raising and lowering operations.

The four-screw electrically-operated drop pit table, originally approximately 8 feet in width, also has further developed. The width was reduced in some cases for trailer wheels and single pairs of engine truck wheels. In most instances the width was increased to the extent that two pairs of driving wheels or complete engine and tender trucks could be dropped. A platform top between rails became regular equipment and today a table of the four-screw type can be obtained to meet special requirements, such as varied capacity, power racking, two hoisting speeds, and platform over nineteen feet in width for the dropping of complete four-wheel trailer truck, booster equipped. The modern four-screw electric drop pit table has taken on additional improvements which add to its value in rendering service, such as nested tops and swing gates. The last mentioned have so many advantages that they will be touched on briefly.

In order that complete six-wheel tender trucks or two or four-wheel trailer trucks with boosters can be dropped complete on a platform top approximately ten feet six inches wide, single or double shoulder pits are placed beside the main drop pit. These shoulder pits are about forty inches deep and of a width to suit the needs. These pits are equipped with swing gates pivoted to their side walls, self-supported at their outer ends, and equipped with rails on their tops. When swung to "out" position and locked, they serve as bridges over which the locomotive is run.

After the engine has been moved over the shoulder pits and spotted on the platform top, the gates are swung inward, butterfly fashion, against the side walls of the shoulder pit. The platform top, with its load, is lowered to clear the locomotive or tender. Any parts of the load protruding beyond the ends of the platform top have no interference because of the shoulder pits. For regular wheel dropping arrangements, the swing gates are merely retained in "out" position.

## Special Points of Advantage

Because of the use of four elevating screws, the load may be safely held at any height of the table top.

Because of capacity and structure, shoes, wedges, and binders may be applied with drivers, all in one operation, eliminating manual labor.

If the driver drop pit is properly located, and spans more than two tracks, it eliminates the need of additional drop pits for trailers and engine truck wheels.

The following "Wheel Removing" work is possible with this table:

1. Change one or two pairs of drivers.
2. Drop one or two pairs of drivers a short distance for box, journal or frame work.
3. Drop a single pair of engine truck wheels at one operation.
4. Drop a single pair of engine trailer wheels.
5. Drop a single pair of tender truck wheels.

6. Drop and change a complete two or four-wheel engine truck.
7. Drop and change a complete two or four-wheel trailer truck.
8. Drop and change a complete six-wheel tender truck.
9. Drop and change complete booster equipped trailer or tender trucks.

(Operations 8 and 9 are made possible through the use of auxiliary shoulder pits and swing gate.)

### General Requirements

The depth and size of pit should be governed by the class of power handled. It should be deep enough to handle the largest wheel along the pit clear of all rail cover supports, and should be wide enough to allow side clearance for man to pass around the dropped wheels.

It is imperative to have the pit well protected against men falling into pit when it is in operation, by means of safety gates or chains, and when pit is not in use it must be fully and strongly covered over to prevent accidents. An overhead crane, jib crane, mono rail and hoists, or a portable crane truck, is necessary to remove this pit covering.

The floor around pit must be of strong rigid construction to resist heavy wear due to handling these heavy wheel and other loads. This may be of reinforced concrete, wood block or asphalt on concrete base.

It is essential that lighting be as nearly perfect as possible. This can be accomplished by flood lights or other good overhead lights, and recessed side light in pit walls, together with ample outlets for plugging in extension cord lights.

No special heating necessary other than that provided for the balance of the house.

It is desirable to install, if possible, a service track or tracks to run between the tracks serving the table, these to extend out through end of enginehouse into back shop instead of the regular pit track. This will allow the full use of the drop table on all tracks served and still allow for the removal of wheels and other heavy parts direct into shop. To accomplish this requires, usually, some special roof carrying trusses in order to clear the floor of posts.

It is also advantageous to extend one of the tracks serving table out through end of enginehouse into back shop (if available) so as to facilitate handling of drivers, other wheels and heavy loads. If back shop is of sufficient size, an engine may be moved over this track into this shop.

It is desirable to construct the stalls at the drop table location longer than the balance of the stalls of the house so that more use of the table can be had, and with closed doors in the winter months. This requires careful study as to proper location of table in the stalls to be served.

It is very essential to provide adequate drainage to pits to assure a satisfactory working condition in pit and to protect against damage to the electrical part of this equipment.

### Selection of Drop Table

There are many variables, such as amount of repair work performed in engine houses on different railroads, also differences in class of work done in different engine houses on the same railroad; also, some houses have a back shop or main locomotive shop available.

The following assumptions are based on a thirty-stall active enginehouse facility to include a comparatively small but otherwise fully equipped back shop, and responsible for and handling light and heavy running repairs, including general inspection between shopping. (This would include Class 3, 4, and 5 repairs.)

There should be a drop pit available serving two tracks for handling engine trucks; one two-track pit for drivers and trailers, and one two-track pit for tender trucks (see typical sketch, Plan No. 1); or one three-track pit so located and constructed as to take care of all the wheel work (see Sketch No. 2). A plan, cross and longitudinal section are shown on Plan No. 3. These views show the wheels have been removed from the pit at the right and are being released on the stall to the left, raising one top above another, with the center track still in service.

## Appendix D

## (8) CAR PAINT SHOPS

A. G. Dorland, Chairman, Sub-Committee; B. Elkind, A. T. Hawk, A. S. Kent, H. C. Lorenz, W. S. McFetridge, F. E. Morrow, V. B. W. Poulsen, W. A. Radspinner.

Questionnaire relative to various features of car paint shops was sent to representative railroads. Replies were received from thirty-two railroads, two of which sent no information; the other thirty replies show a wide variance of recommendations and the following is a summary of these replies.

Car paint shops for freight cars are recommended by twenty-one railroads, and five railroads say they are unnecessary, two say it depends on climatic conditions and two are non-committal. Reasons given for the necessity of a freight car paint shop are many; it avoids delays on account of cold or wet weather; a better and more lasting paint job can be procured when the surface is dry and not too cold; therefore it promotes efficiency and economy.

Car paint shops for passenger cars are recommended by twenty-nine railroads of the thirty replying, the other road is non-committal (having no passenger business.) The reasons for this shop are practically the same as those given for freight car shops with the additional reasons that an even temperature is recommended and that dust and dirt can be kept out, giving a much better finish to the coaches.

Twenty-seven railroads recommend separate shops for painting freight and passenger cars; one railroad says that this is unnecessary, and one does not have enough work for two shops. The class of work is different and the class of paint used is different; when painted by the spray process, paint will get on adjacent cars. Most railroads use entirely different types of work on coaches. All railroads use either varnish or lacquer and many use both; two railroads report using enamel; therefore separate shops are advisable.

The method of preparing cars for painting are varied; for wood freight cars ten railroads have no preparation, sixteen scrape wood cars or use wire brush or both, two burn off the old paint and two wash wood cars; for steel freight cars eighteen sand blast, seven scrape or use wire brush, and two wash cars; for wood passenger cars twenty burn off old paint, five wash and four use brush or scrape; for steel passenger cars eighteen use sand blast, five wash, two use paint remover and five scrape or use wire brush.

While not necessary it is advisable to provide space to do this cleaning outside of the paint shop as the dust and dirt are not conducive to a good paint job; however, to prevent corrosion on steel cars, they should be moved into the shop immediately after cleaning and the first coat of paint applied.

Painting of cars by the spray process is playing an important role in shop operation and shops should be arranged for such work. Where painting is not done by spraying, permanent scaffolding should be provided. These scaffolds should be adjustable and easily operated.

The size of the paint shop naturally depends on the number of days the car must be in the shop, and also the number of cars painted annually. The length of time in the shop depends on the amount of cleaning done in the shop, the number of coats, and the stenciling.

The replies received show the following for freight cars: minimum time in the shop two days and maximum time five days, the average of all roads reporting being three days; for passenger cars the time varies from five days to twenty-one days, the average being twelve and one-fourth days.

From replies received the required capacity of shops in relation to the number of cars in operation was figured on a percentage basis, using a five and one-half day week. For freight car paint shops these replies varied from 0.04 per cent to 0.67 per cent the average being 0.19 per cent. For passenger car paint shops these percentages varied from 0.44 per cent to 4.46 per cent, the average being 1.91 per cent.

The style of shop depends on the amount of the work to be done as well as the layout of car repair shops and the available space for paint shops. Seventeen railroads prefer longitudinal shops for freight cars and six prefer transverse shops. For passenger car paint shops seven prefer longitudinal shops, and fifteen recommend the transverse type. Longitudinal shops should be opened at both ends and transverse shops should have a transfer table unless they are short enough to be served by a ladder track.

The car paint shops should be constructed entirely of fireproof material, with a concrete floor. All shelving should be non-combustible. The shops should be well lighted both naturally and artificially; vapor proof globes should be used; all belting should be eliminated in order that the production of static electricity may be minimized. These shops should be heated and ventilated by the most modern methods; artificial ventilation by fans and blowers if used should provide for circulating all the air in the shop. Especially in lacquer room, openings should be provided at the floor as well as at the ceiling and corners, special attention being given to the specific gravity of the vapors. Fan blades should be rigid and made of non-sparking material, with ample clearance to avoid creating fire by friction, necessary allowance being made for ordinary expansion and loading to prevent contact between moving parts and the duct. Special attention should be paid to the removal of spray paint fumes as fast as they are liberated. This promotes safety and will increase the efficiency of the labor and in addition it will minimize the danger of possible explosion (some lacquers are very combustible.) One manufacturer of paint and varnish recommends that a grate with suction fan be placed beneath each car to carry off the heavier fumes.

Fire hazards are always present in the use and storing of paints and varnishes and these hazards are increased by the use of some lacquers and by the spraying process now in use in most shops.

Six railroads recommend the washing out of the lacquer room monthly, ten railroads weekly, three daily, and one railroad washes out after each lacquer job. For the entire paint shop two railroads wash out annually, five semi-annually, four monthly, four weekly, the others wash out as often as needed. For this reason the concrete floor should have a smooth surface and good drainage; sixteen railroads say this floor should be waterproofed to facilitate cleaning and sixteen recommend that the corners be rounded for the same reason. In old shops with wooden floors the same should be waterproofed.

It is preferable to have the paint stored in a separate building but where this is undesirable, the storage room should be in a room separated from the main shop, this room being cut off from paint shop by standard fire walls and approved fire doors. One railroad recommends underground tanks for paint storage.

Twenty-six railroads recommend separate rooms for the applying of lacquers, said rooms being separated from main shop by standard fire walls and self-closing fire doors.

All electric wiring should be in conduit and it is advisable to have all electric switches for lights, fans or other equipment located in a separate room away from the paint fumes so that there is no danger of an electric spark.

All car paint shops should be provided with approved automatic sprinkler system and a sufficient number of fire extinguishers as well as any other fire protection deemed necessary by local conditions.

The track centers recommended in the replies vary from eighteen feet to twenty-five feet but the average for both freight and passenger shops is twenty feet and the Manual now recommends twenty feet. The distance recommended between the center line of the outer track and the face of the wall varies from six feet to twenty-five feet, the average being twelve feet and nine inches.

The minimum distance recommended between ends of couplers of cars on the same track varies from thirty inches to thirty feet, with the average for freight cars eight feet and for passenger cars nine feet.

The minimum distance between end of coupler and face of end wall; the replies for freight car shops vary from three feet to fifteen feet the average being ten feet five inches; for passenger cars the recommendations vary from three feet to twenty-five feet, the average being eleven feet.

## REPORT OF COMMITTEE XIV—YARDS AND TERMINALS

*Committee.*

### *To the American Railway Engineering Association:*

Your Committee on Yards and Terminals respectfully presents reports covering the following subjects:

(1) Revision of Manual (Appendix A). It is recommended that revisions relating to (a) freight yards and (b) track scales be approved for publication in the Manual. It is further recommended that the section of the Manual entitled "Specifications for the Manufacture and Installation of Motor Truck, Built-in, Self-contained and Portable Scales for Railway Service" (pages 1034-1050) be withdrawn.

(2) Grain Elevator Storage Yards and Plant Tracks (Appendix B). It is recommended that the report be received as information.

(3) Hump Yards (Appendix C). It is recommended that the report be received as information.

(4) Co-ordination of Facilities at Rail-and-Water Terminals. Progress is reported on the assignment.

(5) Scales Used in Railway Service (Appendix D). It is recommended that the report be received as information. It is further recommended that the specifications contained herein be used during the coming year in lieu of the corresponding Manual material, withdrawal of which is recommended under Item 1, above. It is the present intention of your Committee to submit as Manual material next year the material submitted herewith as Appendix D, revised as may be desirable.

(6) Bibliography (Appendix E). It is recommended that the data be received as information.

(7) Expediting of Freight Car Movements through Yards (Appendix F). It is recommended that the report be received as information.

Respectfully submitted,

THE COMMITTEE ON YARDS AND TERMINALS,

M. J. J. HARRISON, *Chairman*.

## Appendix A

## (1) REVISION OF MANUAL

M. J. J. Harrison, Chairman, Sub-Committee; J. E. Armstrong, W. F. Cummings, E. H. Fritch, W. H. Giles, E. M. Hastings, H. L. Ripley, H. M. Roeser, C. U. Smith and E. E. R. Tratman.

PROPOSED REVISION OF SPECIFIED ITEMS OF SECTION OF MANUAL  
COVERING FREIGHT YARDS*(Present Form)*

(1) Freight yards are essentially supplementary units and should be so designed and operated in relation to each other and to the lines tributary to them as to give the most economical results for the railway as a whole.

(5) The type of yard which should be adopted in any given case depends upon the traffic to be handled through it.

(a) A single flat yard is adapted for handling traffic where the total number of cars is small and the number of switching cuts per train is also small.

(b) A double flat yard is adapted for handling traffic where the total number of cars is large but the number of switching cuts per train is small.

(c) A gravity yard or a hump yard is adapted for handling traffic where the total number of cars is large and the number of switching cuts per train is also large—also in special cases where the total number of cars is relatively small but normally received in a short period of time, and the number of switching cuts per train is large and must be made promptly so as to pass the cars through the yard in a limited time.

(23) The number of classification tracks should be such that there will be at least one available for each classification to be made in the yard.

(25) In a hump yard where cars of single classifications accumulate rapidly enough to permit of forwarding them in whole trains, the classification tracks may be used as departure tracks with their lengths determined accordingly.

(28) The location of the sorting yard should be such that mixed cuts may be

*(Proposed Form)*

(1) Freight yards are essentially supplementary units and should be so located, so designed and so operated in relation to each other and to the lines tributary to them as to give the most economical results for the railway as a whole.

(5) The type of yard which should be adopted in any given case depends upon the traffic to be handled through it.

(a) A single flat yard is adapted for handling traffic where the total number of cars is small and the number of switching cuts per train is also small.

(b) A double flat yard is adapted for handling traffic where the total number of cars is large but the number of switching cuts per train is small.

(c) A gravity yard or a hump yard is adapted for handling traffic where the total number of cars is large and the number of switching cuts per train is also large—also in special cases where the total number of cars is relatively small but normally received in a short period of time, and the number of switching cuts per train is large.

(d) In special cases, due to the location of the yard, the character of traffic, or the arrangement of schedules, it may be necessary to provide a double flat yard or a hump yard, because of limited time for handling.

(23) The number of classification tracks should be such that there will be at least one available for each important classification.

(25) Where cars of single classifications accumulate rapidly enough to permit of forwarding them in whole trains, the classification tracks may be used as departure tracks with their lengths determined accordingly.

(28) The location of the sorting yard should be such that mixed cuts may be

*(Present Form)*

moved from the classification yard, sorted, and moved directly to the departure yard without interfering with the operation of the main hump.

(50) Scale tracks should be so located that before cars are classified they may be weighed with a minimum of movement and delay, and where the number of cars to be weighed may exceed 30 in one hour, should be located on gradients such as to permit weighing of cars in motion; a track parallel to the scale track should be provided for non-weigh traffic.

*(Proposed Form)*

moved from the classification yard, sorted, and moved directly to the departure yard or departure tracks without interfering with the operation of the main hump.

(50) Scale tracks should be so located that weigh cars can be weighed with a minimum delay to yard operation. Where the number of cars to be weighed may exceed 30 in one hour, the scale tracks should be located on gradients such as to permit weighing of cars in motion. A track parallel to the scale track should be provided for non-weigh traffic.

## PROPOSED REVISION OF RULES FOR THE LOCATION, MAINTENANCE, OPERATION AND TESTING OF RAILWAY TRACK SCALES

### Section I—LOCATION

1.—**General Conditions.**—The proper location of track scales depends principally on the following conditions:

(a) **The volume of traffic to be weighed in comparison with that switched over the scales and not to be weighed.**—The presence of the scale in a much used track is a source of increased cost of maintenance and difficulty in inspecting and testing as well as dangerous to trainmen. In general, in yards not operated by gravity, the scale should not be located in a main drilling lead unless the number of cars to be weighed exceeds 60 per cent of the total number of cars handled or unless the total number of movements over the main drilling lead is comparatively small.

(b) **Whether the scale is to be equipped with dead rail or relieving gear.**—Dead rails should be provided for four-section scales.

(c) **Whether a runaround track will be installed for switching with a separate track for weighing.** Where spot weighing is done, the runaround track is desirable. If cars are to be weighed as classified, the weighing track need be only long enough to clear the dead rail switches. If cars are to be weighed in solid cuts, the weighing track should be long enough to hold a cut of cars to be weighed, both before and after being weighed, in order not to block operation of other tracks while weighing is being done. The weighing track may be located alongside of the drilling track, alongside of the ladder or on an outer yard track.

(d) **Whether cars are to be weighed spotted or in motion.**—If cars are to be weighed in motion the scale must

### Section I—LOCATION

1.—**General Conditions.**—The proper location of track scales depends principally on the following conditions:

(a) **The volume of traffic to be weighed in comparison with that switched over the scale and not to be weighed.**—The presence of the scale in a much used track is a source of increased maintenance cost and difficulty in inspecting and testing as well as dangerous to trainmen. Except in special cases, the scale should not be located in a drill track unless the number of cars to be weighed exceeds 60 per cent of the total number of cars handled or unless the total number of movements over the drill track is comparatively small.

(b) **Whether the scale is to be equipped with a dead rail.**—Dead rails should be provided for all scales not designed to support the heaviest locomotives likely to run over the scale rails.

(c) **Whether cars will be switched to a separate track for weighing.**—Where spot weighing is done, a runaround track is desirable. If cars are to be weighed as classified, the scale track need be long enough only to clear the dead rail switches. When a scale track is also a body track, it should be twice as long as the longest cut of cars to be weighed, in order not to block operation of other tracks while weighing is being done. The scale track may be located alongside the drill track, alongside the ladder track, or may be an outer body track.

(d) **Whether cars are to be weighed spotted or in motion.**—If cars are to be weighed in motion the scale must

*(Present Form)*

be on a gradient in the drilling track at the head of the classification yard.

(e) The cost of extra switching when the scale is not located on the lead to the classification tracks.—Ordinarily the cost of the extra switching may be ignored when the integrity of the weights would be affected.

(f) The cost of maintenance when the scale is located on the lead to the classification tracks and only a small proportion of the cars are to be weighed.

(g) The necessity for quick dispatch of cars that are weighed.

2.—Position of Live and Dead Rails.—Live rails should be on the offset line and the dead rails straight unless a large portion of the cars are to be weighed. For motion weighing the offset should be divided, unless the resistance is equalized by means of a spring switch.

3.—Gradients for Motion Weighing.—Note.—Attention is called to the following provision of the "National Code of Rules Governing the Weighing and Re-Weighing of Carload Freight"—A.R.A. Circular 1433, May 29, 1914, approved by the I.C.C., June 9, 1914.

"Rule 3-c—Cars may be weighed in motion only when uncoupled and free at both ends and alone upon scales properly designed for weighing in motion and in charge of a competent weighmaster."

(a) Gradients above the Scale.—The distance and gradients from the apex of the hump to the higher end of the scale should be so related to the length of the scale and the gradient of the scale rails that a minimum weighing time per car of four seconds will be secured for free running cars.

(b) Gradients across the Scale.—The gradient of the scale rails should not exceed one per cent, and the gradient of the track for at least ten feet in each direction from the scale should be the same as that of the scale rails.

(c) Gradients below the Scale.—The gradients of the track and the lengths of such gradients below the scale should be such that cars will run by gravity as far away from the scale as desired when their speed over the scale does not exceed that necessary to provide a weighing period of four seconds. Where local conditions make it advisable for car riders to take cuts of two or more cars into the classification yard, the gradient of the scale rails should

*(Proposed Form)*

be on a gradient in the drill track at the head of the classification yard.

(e) The cost of extra switching when the scale is not located on the lead track.—Ordinarily the cost of the extra switching may be ignored when the integrity of the weights would be affected.

(f) The cost of maintenance when the scale is located on the lead track and only a small proportion of the cars are to be weighed.

(g) The necessity for quick dispatch of cars that are weighed.

2.—Alinement of Live and Dead Rails.—

(no change in body of item)

(no change)

(no change)

(no change)

(b) Gradients across the Scale.—The gradient of the scale rails should not exceed one per cent, and the gradient of the track for at least ten feet in each direction from the scale should be the same as that of the scale rails. (See Section II, Item 12.)

(c) Gradients below the Scale.—On the assumption that the speed of cars over the scale will permit a weighing time of four seconds, the track gradients below the scale should conform to the A.R.E.A. recommendations for the class of yard. (See A.R.E.A. Proceedings, Vol. 33, pp. 114 and 115). Where local conditions make it advisable for car riders to take cuts of two or more cars into the classification yard, the gradient of the scale rails should ex-

*(Present Form)*

extend for at least 100 and preferably 200 feet below the scale to enable weighed cars to be assembled in cuts without excessive impacts and to permit all cars involved to be free of the scale when impacts occur.

**4.—Runoff Gradient for Spot Weighing.**—When a scale is installed not in connection with a hump, it is desirable that it be high enough to permit cars to run away from the scale by gravity after being weighed.

## Section II—MAINTENANCE AND OPERATION

**1.—Numbering Scales.**—All track scales should be numbered and referred to by number and location.

**2.—Scale Shop.**—Extensive repairs to scales, such as the renewal or the sharpening of pivots, should be made in a properly appointed shop.

**3.—Cleaning.**—When scales are in service regularly, scale parts, substructure and foundations should be cleaned at least twice a month, and when exposed to the elements, or otherwise so located that they are liable to become clogged with ice or dirt, should be cleaned oftener.

**4.—Rust Preventive for Pivot and Bearing Steels.**—The best rust preventive obtainable should be applied to pivot and bearing steels, but it should be so applied as not to interfere with the proper working of the scale.

**5.—Removal of Ice.**—If ice obstructs the action of the scale, salt should not be used to melt it; artificial heat should be used.

**6.—Standing of Equipment Prohibited.**—Equipment should not be allowed to stand on the scale, except when being weighed.

**7.—Restrictions to Use of Live Rails.**—Engines or similar heavy equipment should not be passed over the live rails, except on authority of the department having supervision over the installation and maintenance of scales. The unnecessary passing of cars over the live rails should be prohibited. Weighed cars which have passed beyond the dead rail switch must not be returned over the live rails. The dead rail switches should be set for the dead rail track except when cars are being weighed.

*(Proposed Form)*

tend for at least 100 and preferably 200 feet below the scale to enable weighed cars to be assembled in cuts without excessive impacts and to permit all cars involved to be free of the scale when impacts occur.

(no change)

## Section II—MAINTENANCE AND OPERATION

(no change)

(no change)

(no change)

(no change)

**5.—Removal of Ice.**—Ice obstructing the action of the scale should be removed by heat and not by application of salt or any other chemical.

(no change)

**7.—Restriction to Use of Live Rails.**—Engines or similar heavy equipment should not be passed over the live rails, except on authority of the department having supervision over the installation and maintenance of scales. The unnecessary passing of cars over the live rails should be prohibited. Weighed cars which have passed beyond the dead rail switch must not be returned over the live rails. The dead rail switches should be set for the dead rail track except when cars are being weighed. When pushing off the scale cars which have been stopped for weighing or other purpose, impact must not occur at a speed greater than two miles per hour.

*(Present Form)*

8.—**Cars Restricted to Live Rails or Dead Rails Only.**—Cars on the live rails must not be moved by cars or engines on the dead rails or vice versa. Cars must not be moved over the scale with one truck on the live rails and another truck on the dead rails.

9.—**Use of Sand and Injector by Enginemen Prohibited.**—Enginemen must not apply sand or use the injector when on the scale. The slipping of engine drivers on either live or dead rails is injurious to the structure and should be avoided.

10.—**Weigh-beam.**—The weigh-beam should be balanced before the scale is used. When not in use it should be secured by the beam catch and with the poise set at the highest graduation.

11.—**Stopping Cars on Scales.**—Cars should not be stopped on the scale by impact, by the sudden application of brakes or by throwing obstructions under the wheels. When pushing off the scale cars which have been stopped for weighing or otherwise, impact must not occur at a speed greater than two miles per hour. When necessary for any reason to run cars over the live rails, the speed should not exceed four miles per hour.

12.—**Automatic Weighing and Recording.**—Where automatic weighing and recording devices are used it is absolutely necessary that both the scale and the automatic devices be in first-class condition, with properly maintained approach track, and cars must be run at a slow rate of speed with particular attention to steadiness of motion which is essential to obtaining best results.

13.—**Locking Scale Houses.**—Scale house and beam boxes must be kept locked when not being used.

14.—**Inspection by Weighmaster.**—The weighmaster should familiarize himself with the construction of the scale and make inspections at such intervals as are necessary to determine whether or not the scale is in proper working condition. The weighmaster and anyone appointed to inspect and clean the scale should be properly instructed, and it is desirable that they be present with the scale inspector when the scale is tested.

*(Proposed Form)*

(no change)

9.—**Use of Sand and Injector.**—The injector must not be used when an engine is over the scale. The slipping of engine drivers on the scale or dead rails is injurious to the structure, but only a sufficient amount of sand to provide the necessary traction should be applied.

10.—**Weigh-beam.**—The weigh-beam should be balanced before the scale is used. When not in use it should be secured by the beam lock and with the poise set at the maximal graduation.

11.—**Stopping Cars on Scales.**—Cars should not be suddenly stopped on the scale by impact or chocking.

12.—**Automatic Weighing and Recording.**—Where automatic weighing and recording devices are used, the scale rails should be smooth, straight, and without joints throughout their entire length. Surface and alinement must be preserved between the ends of the approach and scale rails. The gap between the approach and scale rails should not exceed  $\frac{3}{4}$  in., and should be protected against change by the use of expansion joints in the approach track or other suitable means. The approaches should be maintained smooth so that cars will not reach the scale rails surging on the springs or swaying sidewise. Smooth rolling is essential to the best results. (See Section I, Item 3).

(no change)

(no change)

*(Present Form)*

15.—**Painting.**—The scale mechanism and structural steel should be painted often enough to prevent corrosion.

## Section III—TESTING

1.—**Tests with Single Test Cars.**—Track scales in regular car weighing service should be tested at least every three months with a test car weighing not less than 30,000 lb.

2.—**Graduated Tests.**—Scales when installed and periodically thereafter should be given a graduated test with two or more test loads up to the weight of the heaviest cars normally weighed. The frequency with which such graduated tests should be made depends on the design, capacity and method of installation of the scale used, the wear of scale pivots, and the amount of weighing performed.

3.—**Weekly Tests.**—A test should be made each week by weighing a heavily loaded freight car with as short a wheel base as is obtainable on each end and center of scale. When the scale is equipped with an automatic weighing attachment the car should, in addition to the above, be weighed spotted on the trip end of the scale and in motion with the automatic attachment connected. A report of these tests should be sent to the officer in charge of scales and weighing.

4.—**Daily Tests.**—In addition to the above, a daily test should also be made on each scale equipped with an automatic attachment, by weighing a car spotted on the trip end of the scale with the beam, also in motion with the automatic attachment connected. A book record of this and other tests should be kept by the weighmaster.

5.—**Adjustment.**—Track scales should be kept in the closest possible adjustment, and a scale should be considered inaccurate when it cannot be adjusted, and such adjustment maintained to within two lb. to 1000 lb., in excess or deficiency, when distributed test is made with two or more test loads. When only concentrated sectional tests are made, the maximum error for any position of the test load should not exceed three pounds to each 1000 lb. of test load used.

*(Proposed Form)*

(no change)

## Section III—TESTING

1.—**Test Frequency.**—Track scales in regular car weighing service should be tested at least every three months. The frequency with which tests should be made depends upon the amount of weighing performed, the character and amount of maintenance attention given the scale, and the consistency or lack of it in results of successive tests.

(omit)

2.—**Weekly Tests.**—

(no change in body of item)

3.—**Daily Tests.**—

(no change in body of item)

(omit)

*(Present Form)***Section IV—EQUIPMENT FOR TESTING**

1.—**Standard of Mass.**—The standards of mass for testing scales should be derived from primary weights, verified by the U. S. Bureau of Standards, to within what is known as their "Class B Tolerance". Such weights can be obtained either direct or through scale manufacturers. The 50-lb. secondary or working cast iron weights, which are transported from place to place and used directly in testing scales, should be rectangular, and of such design as to facilitate stacking, they should be free from pockets, blow holes, etc., which are liable to catch and hold foreign matter. No adjusting cavity or cavities in the bottom of the weights should be permitted.

These weights should be properly painted, surfaces maintained in good condition and be tested and adjusted in comparison with master weights, which have been verified to within "Class C Tolerance". The working weights shall be adjusted to within 25 grains and maintained to within 100 grains of their true values.

**NOTE.**—The standards for testing scales in the Republic of Mexico must be in accordance with the metric system standards and will be verified by a Federal scale inspector in accordance with the Federal laws.

2.—**Even Arm Balance and Master Scales.**—It is desirable for verifying or sealing test weights and test cars to have, in addition to standards of mass prescribed above:

(a) An accurate even arm balance of 100 lb. capacity in each pan, sensitive when loaded to two grains.

(b) A master scale.

(there is no present Section V)

(For paragraphs of Section V not quoted here, see pages 433, and 434, herein.)

6.—**Scales with Automatic Weight Recording Attachments.**—For scales equipped with automatic weight recording attachments, the test procedure specified herein should be followed with the attachment connected. If the errors found in

*(Proposed Form)***Section IV—EQUIPMENT FOR TESTING**

1.—**Standard of Mass.**—The standards of mass for testing scales should be derived from primaries verified by the U.S. Bureau of Standards to within what is known as its class B tolerance. The working standards used in compartment type test weight cars should be rectangular and of such design as to facilitate stacking. They should be free from blow holes, pockets, and the like, which may collect foreign matter. No adjusting cavities in the bottoms of weights should be permitted. The working standards should be properly painted, and adjusted correctly within 25 grains of their nominal values. The surfaces shall be maintained in good condition, and the true value of the weights shall be maintained correctly within 50 grains of their nominal values.

**NOTE.**—The practice of control just described applies within the boundaries of the United States. In the Dominion of Canada and the Republic of Mexico, the practice shall be amended as required by law or regulation in the respective National jurisdictions or their civic subdivisions.

2.—**Even Arm Balance and Master Scale.**—It is desirable for verifying or sealing test weights and test cars to have, in addition to standards of mass prescribed above.

(a) A balance of 50 lb. capacity in each pan, whose arms are equal within one part in 350,000, and whose sensitivity is capable of adjustment so that two grains added to either pan when the balance is fully loaded will move the indicator a minimum of one division on the graduated scale.

(b) A master scale.

**Section V—DEFINITION OF A STANDARD TEST OF A RAILWAY TRACK SCALE**

(Follow material appearing on pages 200–202, Vol. 34, A.R.E.A. Proceedings, with the following exceptions—)

6.—**Scales with Automatic Weight Recording Attachments.**—For scales equipped with automatic weight recording attachments, the test procedure specified herein shall be followed with the attachment disconnected. If the errors in this test

*(Present Form)*

this test exceed the tolerances applicable, or if routine use is made of the scale from time to time with weigh-beam only, the attachment shall be disconnected, the weigh-beam balanced, and the complete test procedure repeated. If the errors now found exceed the tolerances applicable, corrective adjustments shall be made to the scale proper, whereupon the automatic attachment shall be reconnected and the complete test procedure repeated. If the errors now found exceed the tolerances applicable, corrective adjustments shall be made to the automatic attachment. In no case shall any adjustment be made to the lever system of a track scale to correct for inaccuracy shown by the test to be contributed by the automatic attachment, or vice versa. The scale and automatic attachment must be individually correctly adjusted.

8.—**Tolerances.**—Every track scale should be kept in the closest possible adjustment, and the weighing performance should be considered unsatisfactory when the scale is not maintained within the appropriate tolerance as herein set forth.

The formally adopted tolerances to be allowed in excess or deficiency on all track scales except grain-weighing track scales are as follows—

(1) **Manufacturers' Tolerance.**—The manufacturers' tolerance to be allowed on the first field test, after installation corrections, of all new railway track scales shall not exceed  $1/20$  of 1 per cent, or 50 lb. per 100,000 lb., for any position of the test car load on the scale. The minimum test car load to be applied shall be 30,000 lb.

The SR shall not exceed 50 lb.

(2) **Maintenance Tolerance.**—The maintenance tolerance on track scales in commercial weighing service shall be—

(a)  $2/10$  of 1 per cent, or 2 lb. per 1000 lb. of test load, when one test car of seven-foot wheelbase or less is used, the tolerance to be applied to the largest mean of two errors found for different positions of the test car not closer than similar positions on adjacent spans. In no case shall the error at any position exceed  $3/10$  of 1 per cent, or 3 lb. per 1000 lb. of test load.

(b)  $2/10$  of 1 per cent, or 2 lb. per 1000 lb. of test load, when two standard test cars are applied on the scale at the same time and at positions not closer together than similar points on adjacent spans.

(c)  $2/10$  of 1 per cent, or 2 lb. per 1000 lb. of test load, when the wheelbase of the test car exceeds seven feet.

*(Proposed Form)*

exceed the tolerance applicable, or if routine use is made of the scale from time to time with the weighbeam only, the attachment shall be disconnected, the weigh beam balanced, and the complete test procedure repeated. If the errors now found exceed the tolerances applicable, corrective adjustments shall be made to the scale proper, whereupon the automatic attachment shall be reconnected and the complete test procedure repeated. If the errors now found exceed the tolerances applicable, corrective adjustments shall be made to the automatic attachment. In no case shall any adjustment be made to the automatic attachment to correct for inaccuracy shown by the test to be contributed by the lever system, or vice versa. The scale and automatic attachment must be individually correctly adjusted.

8.—**Tolerances.**—Every track scale should be kept in the closest possible adjustment, and the weighing performance shall be considered unsatisfactory when the scale is not maintained within the appropriate tolerance as herein set forth.

The formally adopted tolerances in excess or deficiency on all railway track scales are as follows—

(1) **Manufacturers' Tolerance.**—

(no change)

(no change)

(no change)

(no change)

(no change)

*(Present Form)*

(d) 2/10 of 1 per cent, or 2 lb. per 1000 lb. of test load, on two-section scales.

The SR shall not exceed 100 lb.

(2-a) **Maintenance Tolerances on Track Scales Equipped with Automatic Indicating or Weight Recording Devices.**—When a track scale is equipped with an automatic indicating or weight recording attachment, and test is made with such attachment properly connected to the scale mechanism, the tolerances then to be allowed on the indications of the attachment shall be those specified herein for application when no attachment is used. Provided, however, That the minimum tolerance to be applied in such cases shall be the value of one of the minimum graduations. And provided further, that when the mechanism of the automatic attachment is displaced from its position of equilibrium, with a given load spotted on the scale rails, and then permitted to resume its position of equilibrium, the amount by which it fails to return to such position of equilibrium shall in no case exceed the value of one of the minimum graduations.

**Tolerance of Grain-Weighing Track Scales.**—The "Grain Scale Specifications" published as an appendix to "Rules for the Handling of Bulk Grain in Interstate Commerce and the Filing, Investigation and Disposition of Claims for Loss and Damage incident thereto", issued pursuant to recommendation of the Interstate Commerce Commission, prescribe the following tolerance for grain-weighing track scales—

"Railroad track scales used for weighing grain shall be maintained so that when a test load, consisting of a one-truck short wheelbase test car, standardized on a master scale, is used, the largest algebraic mean of any two errors found for different positions of the test truck shall not exceed one-tenth of 1 per cent, or one pound per thousand pounds of test load applied; provided, however, that no two errors shall be selected corresponding to positions of the test truck equal to or closer together than the distance between the sections of the scale. Moreover, the scale shall be corrected when it is found, on test, that the error exceeds one-tenth of 1 per cent of the test load applied for any position of the test load on the scale. The

*(Proposed Form)*

(no change)

(no change)

(3) **Maintenance Tolerances on Track Scales in which are Embodied or to which are Attached Automatic Indicating or Recording Devices.**—For the respective types of scales and conditions of test, the tolerances to be applied to railway track scales in which are embodied or to which are attached automatic indicating or recording devices shall be the same as those applied to railway track scales independent of such devices, except as herein provided.

(a) If the weight is indicated on a dial or reading face, or by means of a printed impression showing the position of an indicating line with reference to a series of graduations, the tolerance shall not be less than the minimal graduation on the dial, reading face, or printed impression, or one five-hundredth of the capacity of the automatic indicating device, whichever is less.

(b) If the weight indication is a printed record in figures representing the weight of the applied load to the nearest unit or multiple of the unit of weight, the tolerance shall be that applicable to the scale independent of the automatic device, plus 50 per cent of the increment between indications that can be printed by the device.

(4) **Tolerance on Track Scales used for Weighing Grain.**—

(no change in body of item)

*(Present Form)*

manufacturers tolerances on new scales shall be one-half of the above values.

"The sensibility-reciprocal shall not exceed 50 lb. in any case."

Section VI—SPECIFICATIONS FOR  
RAILWAY TRACK SCALE TEST  
WEIGHT CARS

(Follow material appearing on pages 169-172, Vol. 34, A.R.E.A. Proceedings, or pages 58-61, Bulletin No. 356, A.R.E.A., June, 1933.)

Section VII—TEST WEIGHT CARS

1.—For general track scale testing test weight cars should weigh not less than a total of 30,000 lb., nor more than 80,000 lb. For making graduated tests and to simplify computations, cars weighing 80,000 lb. and 40,000 lb., respectively, are suggested. The maximum weight of 80,000 lb. is suggested principally in order to reduce the number of restricted movements due to weight limits on scales, bridges, etc.

2.—Test weight cars should be handled on the rear end of trains, just ahead of the caboose.

3.—Test weight cars should not be kept in trains in yards during switching, but should be so placed that rough handling will be avoided. In no case should these cars be subjected to impact at a speed greater than two miles per hour.

4.—All excess weight, resulting from accumulations of snow or ice, should be removed from test weight cars before they are placed on scales for the purpose of testing or on a master scale for calibration. The use of steam is recommended for this purpose.

5.—Test weight cars should be calibrated on a certified master scale before being started on each general test trip, and not less frequently than once every three months. At the time of calibration the actual weight of the car should be made equal to its nominal weight, which should be a multiple of 10,000 pounds.

6.—Each test weight car should be in the care of but one scale inspector between calibrations, and he should be held personally responsible for the maintenance of the correct weight of each car in his care. To this end, the following rules should be enforced:

(a). No repairs to any test car may be made except in the presence of the scale inspector in charge thereof.

(b). Journals of test weight cars may not be repacked unless directed by the scale inspector in charge thereof.

*(Proposed Form)*

(no change)

Section VII—RULES FOR MAINTENANCE AND TRANSPORTATION  
OF TRACK SCALE TEST WEIGHT  
CARS

(Follow material appearing on pages 198-199, Vol. 34, A.R.E.A. Proceedings.)

**Foreword.**—The purpose of these rules is to establish uniform practice in the maintenance and transportation of track scale test weight cars, to the end of securing uniformity in the quality of track scale test results. The rules are intended to cover all phases of test weight car operation except those incident to testing technic. They are applicable to all cars intended to be maintained at a definite weight, and which are used as standards of mass in testing track scales in either railway or industrial service. For brevity, such cars will be designated subsequently throughout these rules as "test weight cars".

1.—**Classification.**—The circumstances of use require that test weight cars be classified into two major groups, namely, "road test weight cars" and "terminal test weight cars".

(a) Road test weight cars are those required by the circumstances of use to be handled normally in road-haul movements over a considerable territory, in the course of which interchange rules may become applicable.

(b) Terminal test weight cars are those whose field of use is normally within the switching limits of a given locality.

**NOTE.**—The distinction between (a) and (b), above, is ordinarily but not necessarily one of ownership. Railway owned test weight cars will be usually within the first class, and industrially owned cars in the second. Attention is directed to the fact that interchange rules do not require air-operated brakes on test weight cars.

*(Present Form)*

(c) Each test weight car should carry a conspicuous badge plate, visible from either side of the car, and carrying a notice to the following effect:

"Do not oil or repack boxes or make repairs to this car unless directed by scale inspector."

(d) Should any change be made in the weight of a test weight car, it is the duty of the scale inspector to determine the amount of such change and immediately to make suitable correction. If the change in weight cannot be determined satisfactorily, the car should be returned to the master scale for calibration before again being used.

7.—The nominal weight of each test weight car should include the car proper and everything contained therein, excepting only such material as is specifically carried as supercargo. This material, consisting of tools, overclothes, etc., when carried, should be contained in a removable steel box, the outside of which should be stencilled to show that it is not a part of the test load. This box and its contents must be removed from the car when being calibrated and when used for testing track scales.

8.—When a test weight car is returned to the master scale for any reason, the actual weight of the car upon its arrival should be determined and recorded. Any unusual variation between that weight and the nominal weight of the car should be promptly and fully investigated.

9.—After the weight of the car on its arrival at the master scale has been determined, the car should receive any heavy repairs which are needed or may be needed before the next trip to the master scale, and should be thoroughly cleaned. At this time the axle bearings should receive any necessary lubrication and packing; after this has been done the car should be calibrated as outlined in paragraph 5 hereof.

*(Proposed Form)***2.—Weight Control.—**

(a) **General.**—All test weight cars are required to be maintained accurately to their designed or nominal weight values. For this purpose, each car shall be verified and corrected as often as may be required, by comparison with the standards of the United States on a scale designated as a master scale by the National Bureau of Standards. A test weight car shall be considered unsatisfactory as a standard of mass when its actual weight differs from the nominal weight by more than sixteen (16) lb. in excess or deficiency.

**NOTE.**—The foregoing paragraph is intended for literal application within the United States. Within the Dominion of Canada and the Republic of Mexico, it should govern as to permissible limits of variation unless modified by existing law or Governmental regulation.

(b) **Responsibility for Weight Control.**—The scale inspector in charge of each car shall be responsible for its weight control in the interval between successive verifications. It shall be his duty to supervise all repairs and recommend advisable modifications, in addition to and in anticipation of M.C.B. Rules. He shall personally weigh all parts removed and materials added when minor repairs are made enroute between verifications. He shall either attend personally to lubrication or supervise it. Since lubrication is an important factor in weight control, varying in degree with different cars, he shall, with due regard for the requirements of each case, take necessary measures to maintain an adequate supply of lubricant and to keep the weight of the car within the prescribed limits of variation.

(c) **Frequency of Verification Recommended.**—

(1) The frequency required for verifications of a given test weight car will depend upon circumstances of use. Generally, road cars will require verification more frequently than terminal cars. The normal frequency required for any particular case can be determined only by experience.

(2) Road test weight cars, which cover definite territory periodically, should be verified at the beginning and end of each itinerary. If the interval between the end of one itinerary and the beginning of the next is reasonably short, the verification which would normally precede the next itinerary may be omitted. This recommendation presumes that each itinerary can ordinarily be completed without the weight variations resulting from normal use being in excess of the allowable variations.

*(Present Form)**(Proposed Form)*

(3) Except in special cases where facilities for local control are exceptionally good, twice yearly should be considered the minimum frequency for verification of terminal test weight cars.

(d) **Verification following Repairs.**—Any test weight car should be verified following major repairs for damage or wear, and following repairs or alterations of any kind which involve weight changes that cannot be confidently controlled by weighing material removed and applied.

(e) **Classification of Repairs.**—Repairs to test weight cars may be classified as either major repairs or minor repairs.

(1) Major repairs are those of such nature and extent that, following their completion, verification of the test car weight is required to establish its suitability for use. They include removal and/or repair and/or replacement of wheels, axles, roller bearing assemblies, journal boxes, draft gear and couplers; replacement of lost or destroyed parts whose weight is unknown or whose replacement is likely to cause a weight variation greater than that allowable; repairs of a general nature subsequent to damage by derailment, collision, or the like; and painting.

(2) Minor repairs may include lubrication, and replacement of bolts, nuts, grab irons, air hose, air hose fittings, knuckles, brake rigging, journal brasses, springs, or other parts which either are of known weight or can be weighed on removal and replaced with parts of known weight.

(3) **Record of Repairs.**—A historical record describing the nature of all repairs should be maintained. When minor repairs are made and the weight control is maintained by weighing the material removed and applied, the record should itemize parts and weights.

(f) **Semi-elliptical Springs.**—If a test weight car is equipped with semi-elliptical springs, each spring, when installed, should have its weight stamped or otherwise permanently marked on the band. If spare springs are carried, each should be marked with its weight.

(g) **Air Equipment.**—Test weight cars equipped with air-operated brakes should have the equipment inspected, cleaned, repaired if necessary, lubricated and stenciled at the time of verification. In any event, such work must be done at such periods that expiration of the interval allowed as a maximum by M.C.B. Rules for operation without reinspection will not occur while a car is on a testing trip.

(h) **Removing Foreign Material.**—Test weight cars carrying accumulations of

*(Present Form)**(Proposed Form)*

snow, ice or sleet must not be used. Frozen matter may be removed by placing the car in a heated building or by using steam, but not by the use of salt or chemicals. Oil and dirt on the car wheels should be removed by suitable means. Accumulated moisture in closed compartments must be removed whenever circumstances require.

(NOTE.—All compartments and recesses should be made self-draining.)

(i) **Painting.**—Test weight cars should be kept well painted. The finish should have a gloss that can be restored by applying available forms of vehicle polish. Chipped portions of paint surface should be retouched at times of verification.

(j) **Surplus Lading.**—Articles such as car movers, tools, tool boxes, personal effects, etc., must not be included in the nominal weight of a test weight car. One metal chock per car may be so included.

(k) **Inspection preceding Test.**—Test weight cars must be examined by the inspector in charge immediately before each test, with a view to detecting damaged or missing parts or the unauthorized substitution of parts.

(NOTE.—A common operating difficulty is the making of running repairs, such as replacement of brake shoes, knuckles, air fittings, etc., without notification to the scale inspector who is responsible for weight control. It can be offset only by strict vigilance and discipline.)

(l) **Date of Latest Verification.**—This shall be stenciled on both sides of the car.

### 3.—Transportation.

**Yard Handling.**—Test weight cars should be protected from rough handling at all times. Those equipped with roller bearings should not be “humped” without warning against runaways to the hump foreman and switching crews. Impacts at greater speeds than two miles an hour should be avoided. When uncoupled from a train or cut of cars in motion, the brakes should be manned and, after motion has stopped, firmly set.

## DISPOSITION OF OBSOLETE TRACK SCALES

A track scale which has been removed by reason of inadequacy, obsolescence or inaccuracy, should be disposed of in either of the following ways:

(1) Treat as scrap metal after rendering unfit for further use as a scale or parts thereof.

(2) Retain for use as repair parts of existing scales of the same type and size.

## Section VIII—DISPOSITION OF OBSOLETE TRACK SCALES

(no change in body of item)

## DEFINITION OF A STANDARD TEST OF A RAILWAY TRACK SCALE

1.—**Test Equipment.**—A Standard Test Car, as the term is used herein, is a Test Weight Car which is constructed, operated and maintained according to the applicable specifications and rules adopted by the American Railway Engineering Association.

2.—**Test Car Positions.**—The sections of a railway track scale are numbered 1, 2, 3, etc., from left to right when standing at the weigh-beam and facing the scale deck. Normal positions of a test car are designated in order from left to right as—1R, 2L, 2, 2R, 3L, 3, 3R, etc., the numbers representing the sections and the letters, when affixed, indicating that the body of the car lies to the left or right of the section with one pair of wheels directly over the section. The following are standard combinations of normal test car positions (taking a four-section scale as an example), any one of which combinations may be used when making a standard track scale test.

- (a) 1R, 2, 3, 4L.
- (b) 1R, 2L, 3R, 4L.
- (c) 1R, 2L, 2R, 3L, 3R, 4L.

When testing a two-section scale, the standard combination of normal test car positions is:

1R, Center, 2L.

3.—**Zero Load Balance.**—Any out-of-balance condition of the scale shall be noted by the scale inspector upon his arrival, and the amount thereof be recorded on the report form. After correcting the out-of-balance condition, if any, and before any adjustment or repairs are made, the scale shall be tested as outlined herein. The zero-load balance shall be checked after each run of each test car across the scale, and any out-of-balance condition thus found shall be corrected, and the amount thereof shown on the test report. This correction shall be made by moving the balance ball or other balancing accessories of the weigh-beam. The scale indications shall be read to the nearest 10 lb., and the several readings shall be so recorded on the report form as clearly to indicate that they represent the weighing condition of the scale "as found" or "as left".

4.—**Sensibility-Reciprocal.**—The sensibility-reciprocal (SR) is the change in load required to turn the weigh-beam from a horizontal position of equilibrium in the center of the trig loop to a position of equilibrium at either limit of its travel. In the case of track scales, the construction of which includes a weigh-beam and multiplying indicator connected thereto, the condition of balance of which is shown by the position of the indicator with reference to the center of a series of graduations, and where the total movement of the indicator exceeds one-half inch, the SR is the change in load required to move the indicator tip one-fourth inch from its normal position of balance to a new position of equilibrium.

5.—**Classification of Tests.**—Standard track scale tests are classified as follows, according to the character of testing equipment used:—

**Standard Graduated Test.**—A standard graduated test is one made with two standard test cars weighing, respectively, not less than 30,000 lb. and not less than 80,000 lb. The weight of the light car should approximate one-half the weight of the heavy car. The standard test procedure is as follows:

- (1) Spot one test car at each of the predetermined test positions, and record both the scale indication and the error for each such position.
- (2) Spot the other test car at each of the predetermined test positions, and record both the scale indication and the error for each such position.
- (3) Spot both test cars on the scale rails, separated by such distance or distances as will result in a condition of loading approximately equivalent to that produced by a freight car, and record the positions, the scale indication, and the error.
- (4) Inspect scale, remove binds, do any practicable repair work, and make any advisable adjustments.
- (5) If any defective condition is corrected or any adjustment made, repeat tests Nos. 1, 2 and 3, reversing the positions of the cars in test No. 3 when practicable.

**Single-Load Test—Standard Form.**—The standard form of single-load test is one made with one standard test car, the weight of which is not less than 80,000 lb. The standard test procedure is as follows:

- (1) Spot test car at each of the predetermined test positions, and record both the scale indication and the error for each such position.

(2) Inspect scale, remove binds, do any practicable repair work, and make any advisable adjustments.

(3) If any defective condition is corrected or any adjustment made, repeat test.

**Single-Load Test—Secondary Form.**—The secondary form of single-load test is one made with a test car, the weight of which is less than 80,000 lb. and/or the length of whose wheelbase exceeds seven feet. The test procedure is the same as that for the standard form of single-load test, but the test report must clearly indicate the weight of the test car and the length of its wheelbase.

6.—**Scales with Automatic Weight Recording Attachments.**—(See page 426 herein).

7.—**Test Record.**—The results of the test shall be recorded during the course thereof on a suitable report form. The following information shall be shown:—

- (a) Date of test and signature of inspector.
- (b) Full and complete identification of the scale.
- (c) Classification of test, as determined hereby.
- (d) Identification, nominal weight, and length of wheelbase of each test car used.
- (e) Balance condition and SR as found by the inspector upon his arrival.
- (f) Results of test before any adjustment or repairs are made, with readings and errors to the nearest 10 lb.
- (g) The amount of change in zero-load balance after each run of each test car or cars across the scale.
- (h) The value of the SR under zero load and under maximum applied load.
- (i) Any defective condition found during inspection of the scale.
- (j) Any adjustment made to correct the weighing performance of the scale.
- (k) Any action taken at the time of the test to correct defective conditions found to exist in the scale mechanism or structure.
- (l) Results of test after making adjustment or correcting any defective condition in the scale mechanism or structure, with readings and errors to the nearest 10 lb.
- (m) Recommendations of the inspector, unless these are required to be made separately.
- (n) Any additional information required by the testing agency, and any unusual condition affecting the test.

## Appendix B

### (2) GRAIN ELEVATOR STORAGE YARDS AND PLANT TRACKS

W. H. Giles, Chairman, Sub-Committee; Irving Anderson, J. E. Armstrong, W. O. Boessneck, N. C. L. Brown, M. J. J. Harrison, E. M. Hastings, W. J. Hedley, W. H. Hobbs, Noah Johnson, E. K. Lawrence, L. L. Lyford, C. U. Smith, E. E. R. Tratman and H. M. Waite.

An analysis has been made of the replies to a questionnaire sent to 47 railroads by this Committee, and the result of this analysis is the basis of the Committee's report for this year.

The construction of large grain elevators to be served by a railroad involves special yard design.

Modern grain elevators are equipped for the rapid handling of grain. During the season that the grain is moved from field to storage the railroads are called upon to handle large quantities of the product in a relatively short time.

Cars of grain moving into terminals usually are subject to inspection and reconsignment. The carrier bringing the shipment into the terminal designates certain tracks, called hold tracks, for this purpose. After receipt of advice for disposition, the car is moved from the hold track and classified for further movement. If inspection or reconsignment is not required, the movement to and from the hold tracks is unnecessary.

After reclassification from the hold-tracks, loaded cars destined to an elevator on carrier's rails are ready for delivery to the elevator storage yard or plant receiving tracks as the case may be. In some cases where the elevator is located within a short distance

of the general yard, and sufficient trackage is available, the cars are held and moved directly from classification tracks to the elevator receiving tracks. Where the elevator is located some distance from the general yard, as in the case at ports or outlying industrial districts, and the plant cannot be served from an auxiliary yard, separate storage yards are sometimes provided. A part of an auxiliary or overflow yard adjacent to general yard and convenient to elevator is sometimes used for the handling of the elevator business.

### GRAIN ELEVATORS—GENERAL TYPES

There are three general types of elevator plants, each located, geographically with respect to the class of traffic handled, viz: (1) The rail-to-rail plant, where grain is received by rail for storage and subsequently reshipped by rail; (2) The rail-to-water plant, where grain is received by rail for storage and later reshipped by boats, and (3) The water-to-rail plant, where the grain is received from boats for storage and reshipped by rail. Specific plants may be combinations of these types.

Large rail-to-rail plants are located in most of the principal cities of the central United States and Canada, where the bulk of the grain produced is stored. During recent years, since the inauguration of traffic on some of the principal rivers of the United States, favorably situated rail-to-rail plants have been equipped with auxiliary marine units for receiving and shipping grain by barge.

The rail-to-water plants, and water-to-rail plants are located at the principal ports along the seaboard, Gulf coast, Great Lakes and navigable rivers. Although the primary purpose of these plants is the transfer of grain from rail to boat, or from boat to rail, usually facilities are provided for the occasional reshipment by the same means as received.

### ELEVATOR PLANT TRACKS

The arrangement, number and capacity of plant tracks depends upon the type of plant to be served, the position and extent of elevator receiving and shipping facilities, normal receiving and shipping requirements, and local conditions.

#### Rail-to-Rail Plants

At rail-to-rail plants, separate receiving and shipping tracks are usually provided; at some plants certain tracks are used for both shipping and receiving.

The number of receiving tracks depends upon the arrangement of unloading pits and/or mechanical car unloaders usually located near the "workhouse". The car capacity of the receiving tracks above and below the unloading facilities is, in general, approximately the same, permitting the continuous movement of cars without congestion after being unloaded. Where double ended receiving tracks are provided, loaded cars are placed above the unloading facilities at one end and empty cars are removed at the other. Where spur tracks are provided the loaded cars are pushed to a point above the unloading facilities. As a rule, the carrier's locomotives are not permitted to pass over the unloading facilities or into receiving shed, and idler cars are required properly to place loaded cars on spur receiving tracks.

After the loaded cars are placed on the receiving tracks the elevator forces move the cars to and from the unloading facilities by means of mechanical car pullers, car spotters, or small plant locomotive. In some cases the empty car is moved by gravity after leaving the unloading facilities. A slight descending gradient in the tracks to and from

the unloading point is indicated where car pullers are used. Sometimes an accelerating gradient is also provided immediately below the unloading point.

The car capacity of the shipping tracks above and below the loading point is, in general, about the same and, as in the case of the receiving tracks, permits the continuous movement of cars without congestion after being loaded. At some plants, the receiving tracks are also used as shipping tracks. The placing and removal of cars on shipping tracks, whether double ended or spur, is substantially the same as on the receiving tracks, except that empty cars are placed for loading and loaded cars are removed. The cars, after being placed above the loading facilities, are moved to and from the loading point by the elevator forces with mechanical car pullers or other means.

### **Rail-to-Water Plants**

At rail-to-water plants, the plant tracks are primarily receiving tracks with one or more of these tracks equipped to accommodate the occasional transfer of shipment. A separate shipping track is provided in some cases.

Elevators with their plant tracks located at a congested port occupy valuable property and the space allotted for the track arrangement is somewhat limited. At one rail-to-water plant the receiving tracks are located in two separate parallel groups with the unloading facilities located near one end of the inbound tracks. After the loaded cars are placed in the first group they are moved to the unloading facilities by means of mechanical car pullers and spotters. After leaving the unloading facilities the empty car moves over an accelerating descending gradient gaining sufficient momentum to ascend a gravity switch-back where the car reverses its direction to move through a spring switch into the second group.

The handling of cars to and from receiving tracks at rail-to-water plants is carried out in a manner similar to that at rail-to-rail plants; the method depending upon the track arrangement.

The gradients in the tracks to and from the unloading facilities where mechanical car pullers are used are similar to those of rail-to-rail plants.

### **Water-to-Rail Plants**

At water-to-rail plants, the plant tracks are primarily shipping tracks but usually an unloading unit is located on one of the tracks for the occasional transfer of grain, from car to car.

## **STORAGE YARDS**

Storage yards for the purpose of handling grain elevator business are not provided in all cases. It appears that the location of the elevator plant, with respect to the general yard, influences the necessity for this facility. Where the plant is located some distance from the general yard, and no auxiliary yard is available, a storage yard is sometimes provided. This is particularly true where the plant is located in an outlying district of a terminal.

## **GENERAL**

The capacity of the receiving tracks above and below the unloading facilities, as compared with the number of cars unloaded daily, varies according to the location of the plant. It appears that local conditions influence the extent of the plant track facilities, particularly in congested areas. In some cases the capacity of the plant tracks

compares favorably with the average number of cars unloaded or shipped daily in

I

compares favorably with the average number of cars unloaded or shipped daily; in others, a capacity of about one-half the daily business is indicated. At some plants the capacity is small, compared to the business handled, indicating almost continuous use of switching service.

The number and capacity of shipping tracks at rail-to-rail plants is usually less than that of the receiving tracks, due, partly, to the comparative simplicity of the loading device, which can be installed on receiving tracks to augment the capacity of the shipping tracks, and in general the uniformity of shipping requirements.

Where car unloaders are used, two or more receiving tracks usually converge or are connected with crossovers above and below the unloader to provide additional capacity for this device.

A separate track is provided to serve the power house if one is included in the plant layout. At electrically operated plants of modern design the fuel shipments for use in the drier unit are unloaded into storage bins from an adjacent receiving track in some cases.

At some plants, where a gas locomotive is used for handling the cars, a short track extends from one of the receiving tracks to a small building where the locomotive is housed and repaired.

Statement showing characteristics of 47 grain elevators served by railroads in the United States and Canada is included as information.

Fig. 1 is an example of a rail-to-rail plant with separate storage yard.

Fig. 2 is an example of a rail-to-water plant layout.

## GRAIN ELEVATOR STORAGE YARDS AND PLANT TRACKS

## CHARACTERISTICS OF PLANTS AS REPORTED IN QUESTIONNAIRE

| No. | Served by      | Location            | Local Name          | Capacity (bu.) |            |            | Pits | Undrs. | Legs |          |

## (3) HUMP YARDS

E. M. Hastings, Chairman, Sub-Committee; J. R. W. Ambrose, N. C. L. Brown, H. F. Burch, W. F. Cummings, R. B. Elsworth, R. J. Hammond, G. F. Hand, J. V. Hanna, M. J. J. Harrison, C. P. McCausland, C. H. Mottier, T. R. Ratcliff, H. L. Ripley, W. B. Rudd, W. C. Sadler, E. P. Vroome and H. M. Waite.

There was submitted for the information of the Association at the March 1933 meeting a report covering what is termed the graphic method to be used in designing gradients in connection with the application of car retarders to hump yard operation. Two graphic methods were described, "A" and "B". Your Committee for this year presents for the information of the Association further discussion of the matter, particularly information concerning application under Graphic Method "B". Reference is made to the sub-committee report to the March 1933 Convention (see page 177, Vol. 34 of the Proceedings). Reference is also made to the Fig. 5 accompanying that report showing typical classification yard of fifty tracks. The following application and discussion is based upon this track layout. The figures accompanying this report are numbered numerically as a continuation of the report of last year.

## (I) APPLICATION TO THE DESIGN OF CLASSIFICATION YARD GRADIENTS

Some of the basic principles described in Section I, Graphic Method "B" (see page 183, Vol. 34 Proceedings) are useful in designing gradients when compensation for curvature is desired, since they may be used to portray the approximate car speeds to be expected with various gradients, thereby indicating the locations where compensation should be used. Also they are useful in representing the releasing speeds necessary to secure the proper movement of cars in accordance with their various resistances, thus illustrating some of the problems encountered by an operator and perhaps leading to the most satisfactory design of the gradients.

Fig. 9 and 10 show equivalent gradients which have been drawn to include the curve resistance which may be found in a car running on each of several different tracks which differ either in the amount or location of the curvature and finally show the gradients upon which fairly uniform car speeds may be obtained. The resultant velocity head profile shows also the variation in car speeds which cannot be avoided.

The track arrangements are shown diagrammatically but the lengths of track and curvatures are drawn to scale. Each of the curves including the turnouts which are marked to indicate its central angle. In Fig. 9 four groups of various types of profiles are shown as follows:

(a) A line is drawn at a slope which represents a gradient of 0.22 per cent, equivalent to a resistance of 4.4 pounds per ton for a car running on tangent track. The vertical height  $C_1$  represents the drop which, at the rate of 0.025 ft. per degree of central angle, would be required to compensate for a curve having an included angle of  $7.15^\circ$ , and the line drawn underneath the curve represents an equivalent gradient which includes the curve resistance. A similar equivalent gradient is drawn, using a value  $C_2$  for the curve having a central angle of  $28.76^\circ$  and then the lower series of lines represent a gradient equivalent to the resistance of a car running to track 1. It will be found that results, obtained from using Formula B, as found on page 129, Vol. 33, but with (b) omitted will equal the drop represented by the notation "Formula B".

(b) Similar profiles are shown for track 3.

(c) Similar profiles are shown for tracks 4 and 5.

(d) A composite of the profiles of the above tracks is shown together with gradients designed to provide a fairly uniform speed for the car in running from the last retarder to tangent track but at least so that, regardless of the track over which it runs, it will leave the last retarder with a velocity head of 0.54 ft. (4 m.p.h.) and will arrive on tangent track with the same velocity head. Also it will be noted that the gradients are arranged, so that the compensation has, as nearly as possible, a direct relation to the curvature for which it is added.

In Fig. 10, three groups of profiles are shown to illustrate the gradients derived from a similar study of tracks 21 to 25, inclusive, and if this is done for all tracks the gradients will be designed substantially in accordance with method No. 1 as described in this Committee's report found on page 130, Vol. 33 of the Proceedings.

The graphic method may be of assistance in studying the operation obtained with gradients designed in accordance with the seven methods of application set forth in the above mentioned report. Thus far, in this report, the only resistance considered has been 4.4 pounds per ton but it is obvious that there will be other resistances varying from at least 4.4 pounds per ton to 18.0 pounds per ton (see page 131, Vol. 33 of the Proceedings). If all cars are to be run to clearance at speeds which are suitable for coupling with other cars, the operator must adjust the releasing speed of such car in

accordance with its rolling qualities, the resistances peculiar to each track, and the distance through which it must run before coupling. The problems of an operator will depend upon the range of releasing speeds necessary to satisfy all car resistances encountered and his efficiency on his ability to judge such speeds. Therefore, the various methods of designing gradients should be considered from the viewpoint of releasing speeds.

Fig. 11 shows the two groups of tracks together with the equivalent gradients and track gradients developed in Fig. 9 and 10, these having been plotted from an equivalent point in each classification track where all cars are to have the selected practicable speed of 4 miles per hour (0.54 ft. V.H.). Also there is shown a group of equivalent gradients for a car having 18.0 pounds per ton resistance to represent the hard rolling car. The velocity head values at the last retarder, as measured between the equivalent gradients and their corresponding track gradients, represent the releasing speeds required under various conditions.

### Method 1

This method involves grading each track with its proper amount of curve compensation. The velocity heads of the releasing speeds would be approximately as shown, the range being from 0.54 ft. (4 m.p.h.) to 3.39 ft. (10 m.p.h.) for cars having resist-

inclusive, have profiles the same as tracks 21, 22 and 24. It is obvious that with the conditions named under Method 1 there would be more tracks where acceleration could take place, thereby requiring that the releasing speeds be lowered for a larger percentage of the cars handled.

#### Method 4

This method is a modification of Method 3 in that all tracks in the group are graded in the same plane as the track having the least curvature, which requires that tracks 1 to 5, inclusive, have profiles the same as track 3 and that tracks 21 to 25, inclusive, have profiles the same as track 23. With the conditions named under Method 1, the range of releasing speeds would include 0 m.p.h. (0.54 VH) to 11.2 m.p.h. (4.20 VH) for tracks 1 to 5, inclusive, and 2.5 m.p.h. to 10.6 m.p.h. (3.72 VH) for tracks 21 to 25, inclusive. When compared with Method 1, however, a low releasing speed would be required for a smaller percentage of the cars while a higher releasing speed would be required for a larger percentage of the cars.

#### Method 5

This method involves grading all tracks in the same plane as the track having the greatest curvature which requires that all tracks have profiles the same as track 1. It is

obvious that, with the conditions named under Method 1, there would be even more tracks than under Method 3 where acceleration could take place, thereby requiring a lower releasing speed for a still larger percentage of cars.

### Method 6

This method involves grading all tracks in the same plane as the track having the least curvature which requires that all tracks have profiles the same as track 23. This is a modification of Method 4 and with the conditions named under Method 1 the range of releasing speeds would include 3.3 m.p.h. (0.54 VH) to 11.7 m.p.h. (4.57 VH). It will be noted that with this method there are no tracks where the releasing speed is required to be lower than 3.3 m.p.h. and that in comparison with Method 1 the highest releasing speed is increased only 1 m.p.h.

### Method 7

The accelerative increment to be found in Formula B (see page 130, Vol. 33 of the Proceedings) thus far has been omitted. It is obvious, that a plus value, for the factor b, will decrease while a minus value will increase the releasing speed and that the use of this factor will have its greatest effect on the easy rolling car.

## (II) TIME OR DISTANCE SPACING OF CARS

The humping capacity of any yard may depend upon the frequency at which cars may be released at the crest of the hump which, in turn, is limited by the time or distance spacing required at various locations within the switching area. A graphic representation of time consumed and distance traveled in running cars from the crest to clearance will show the locations where such limitations occur. It is obvious that, within the retarder area, the gradients and retardation can be coordinated so as to permit running all kinds of cars from the crest to entering the last retarder with approximately the same time interval for each car. However, after entering the last retarder considerable variation may occur since various releasing speeds are required.

Fig. 12 illustrates various conditions which may exist when running an easy rolling car to track 1 closely followed by a hard rolling car running to track 2 based on the assumption that each has consumed the same amount of time in running from the crest to the last retarder. Velocity head values, taken from Fig. 11, are plotted to a common base line to show a direct relation between several combinations of car resistances and gradients, as follows:

- (a) Hard rolling car, (0.9 per cent or 18.0 pounds per ton) with curve resistance, running on a non-compensated gradient to track 2.
- (b) Hard rolling car, (0.9 per cent or 18.0 pounds per ton) with curve resistance, running on a compensated gradient to track 2.
- (c) Easy rolling car, (0.22 per cent or 4.4 pounds per ton) with curve resistance, running on a non-compensated gradient to track 3.
- (d) Easy rolling car, (0.22 per cent or 4.4 pounds per ton) with curve resistance, running on a compensated gradient to track 3.
- (e) Easy rolling car, (0.22 per cent or 4.4 pounds per ton) without curve resistance, running on a compensated gradient to track 3.

Time distance curves are calculated by scaling the average velocity heads for small increments of distance, converting them to speed values, dividing these values into the

distance increments, thus determining a time increment, and finally adding each time increment to the preceding total to be plotted in accordance with the distance traversed. Time distance curves (a') to (e') inclusive were plotted from corresponding velocity head profiles (a) to (e) inclusive.

The front and rear ends of a car shown for curve (e') and for part of curve (b') as it has been redrawn to show the relation between them at the clearance point for tracks 2 and 3 when the easy rolling car is stopped in the last retarder and then allowed to run to clear, and when the hard rolling car runs to track 2. It will be noted that for this condition, approximately a 65 second spacing between cars would be required to prevent cornering at the clearance point.

If the easy rolling car has curve resistance and runs as shown in (d') the time spacing would be 18 seconds but if the gradients are non-compensated as shown in (a') and (c') the time spacing would be 12 seconds. Furthermore, if the clearance point is at a greater distance from the last retarder the time spacings for the above combinations are increased.

### (III) Conclusions

No conclusions have been drawn from the above since this report is intended only to describe the graphic method, the special cases having been given to illustrate various applications which may be made. All of the special cases were based on this Committee's report, page 781, Vol. 31.

## Appendix D

### (5) SCALES USED IN RAILWAY SERVICE

H. M. Roeser, Chairman, Sub-Committee; J. E. Armstrong, H. G. Basquin, Alfred Bousfield, A. W. Epright, E. D. Gordon, M. J. J. Harrison, E. M. Hastings, H. O. Hem, E. K. Lawrence and E. P. Vroome.

#### PROPOSED SPECIFICATIONS FOR THE MANUFACTURE AND INSTALLATION OF MOTOR TRUCK, BUILT-IN, SELF-CONTAINED AND PORTABLE SCALES FOR RAILWAY SERVICE

##### Introduction

Motor truck, built-in, self-contained and portable scales for railway service of the kind known to the trade as knife-edge scales are covered by these specifications. The application is basically to scales equipped with weigh-beams. For scales of the automatic indicating and/or recording type, and with automatic indicating and/or recording attachments, the specifications apply to all parts except the mechanism essential to the automatic feature.

##### 1. Information to be Supplied by Purchaser

To assure definiteness in handling proposals and acceptance of material when manufacturers or contractors are required to furnish scales, or are invited to offer bids to furnish scales conforming to the specifications herein, the information indicated in the schedule below must be supplied by the purchaser.

101. State the nominal capacity of the scale and the size of platform.
102. If a motor truck scale, is a plain or registering weigh-beam required?
103. If a built-in scale, is a full-capacity beam required?
104. If a built-in or self-contained scale and a definite ratio is required at the beam tip, state what it is. (See Item 1304.)
105. State the material of which the counterpoise weights are to be made. (See Item 1314.)

106. For motor truck and built-in scales, state what material is required for the platform.

107. If a motor truck scale, is the weigh-bridge to be furnished completely fabricated?

108. If a built-in scale, is the weigh-bridge, platform and coping material to be furnished with the scale?

109. For motor truck and built-in scales, state special requirements, if any, for clearance between the platform and weigh-beam.

110. What installation service, if any, is to be furnished by the firm supplying the scale?

## 2. Classes of Scales

201. The classes of scales covered by these specifications are the following:

(a) **Motor Truck Scales:** A motor truck scale is one designed for the purpose of weighing power-driven highway vehicles and trailers.

(b) **Built-in Scales:** A built-in scale is one of 10,000 or 20,000 pounds capacity, marketed without the frame supporting and containing the main lever system, designed to require preparation of a foundation on the premises where used.

(c) **Self-contained Scales:** A self-contained scale is one enclosed and supported by its own frame, marketed as a complete weighing unit and designed for use in a permanent location.

(d) **Portable Scales:** A portable scale is one mounted on wheels or otherwise designed for easy movement from place to place.

## 3. Capacities and Sizes

### 301. Definitions.

(a) **Capacity:** The capacity of a scale is the heaviest load that can be totally applied to the platform without inducing stresses in any member in excess of those specified in Section 5, the conditions of concentration of loading being those required in Section 6.

(b) **Nominal Capacity:** The nominal capacity of a scale is the largest weight indication obtainable by use of all the reading elements in combination, fractional beams totaling two per cent or less of the remaining reading elements being neglected.

(c) **Size:** The size of a scale is expressed by the dimensions of the platform surface. In rectangular platforms, the first dimension given is that of the platform edge nearest the beam.

302. **Nominal Capacities and Sizes:** The nominal capacities and sizes of scales in the different classes covered by these specifications shall be as given in Tables 1-(a) and 1-(b).

TABLE 1—(a)

### NOMINAL CAPACITIES AND SIZES OF MOTOR TRUCK SCALES FOR RAILWAY SERVICE

| <i>Nominal Capacity<br/>(pounds)</i> | <i>Size<br/>(feet)</i> | <i>Conditions governing selection</i>          |
|--------------------------------------|------------------------|------------------------------------------------|
| 60,000 to 70,000                     | 34 by 10               | For weighing coupled vehicles.                 |
| 40,000 to 60,000                     | 22 by 9                | Usual standard for weighing separate vehicles. |

Special cases may be better suited by selection from the following nominal capacities and sizes.

|                  |                                       |
|------------------|---------------------------------------|
| 60,000           | 24 by 10.                             |
| 40,000 to 60,000 | 20 by 9, 20 by 10, 24 by 9, 24 by 10. |
| 36,000           | 18 by 9.                              |
| 24,000           | 16 by 8.                              |

TABLE 1—(b)

## NOMINAL SIZES AND CAPACITIES OF BUILT-IN, SELF-CONTAINED AND PORTABLE SCALES FOR RAILWAY SERVICE

| <i>Class of Scale</i> | <i>Nominal Capacity<br/>(pounds)</i> | <i>Size<br/>(feet)</i>                   |
|-----------------------|--------------------------------------|------------------------------------------|
| Built-in .....        | 10,000<br>20,000                     | 6 by 5, 8 by 6, 9 by 7<br>8 by 6, 9 by 7 |
| Self-contained .....  | 2,500<br>4,000<br>10,000             | 46 by 38<br>48 by 48<br>72 by 54         |
| Portable .....        | 1,000<br>2,000                       | 18 by 27<br>25 by 32                     |

(In Tables 1—(a) and 1—(b), the intent of the specifications is that minor variations from the nominal capacities and dimensions given for platform sizes are immaterial, and being otherwise in conformance with these specifications, the usually manufactured stock sizes are satisfactory.)

## 4. Plans

401. The purchaser shall, upon his request, be furnished written information showing the material of which scales proposed to be furnished are made, and if any material be not among those to which the safe stresses listed in Section 5 apply, the chemical and physical properties must be given in sufficient detail to permit confident judgment of the safe stresses or factors of safety used in design.

402. For motor truck and built-in scales, the purchaser shall be furnished assembly plans showing the location and size of open holes for field connections and all information necessary for the design and construction of the pit or all parts required and not furnished with the scale. (See also Item 1701.) Upon request in the invitation for bids, the purchaser shall be furnished drawings or descriptions in sufficient dimensional detail to permit the customary design calculations for stresses and to allow adequate checking of the design requirements for construction, finish and workmanship.

## 5. Design Data, Working Stresses, and Formulas

501. In any scale loaded as required in Section 6, the following unit stresses shall not be exceeded. The stresses given include a sufficient allowance for impact.

TABLE 2  
WORKING STRESSES IN POUNDS PER SQUARE INCH

| <i>Material</i><br>Cast Iron (gray),<br>Thickness of section. | <i>Transverse Bending</i> |                    | <i>Direct Stress</i> |                    | <i>Shear and<br/>Torsion</i> |
|---------------------------------------------------------------|---------------------------|--------------------|----------------------|--------------------|------------------------------|
|                                                               | <i>Tension</i>            | <i>Compression</i> | <i>Tension</i>       | <i>Compression</i> |                              |
| 0.25"                                                         | 5000                      | 8500               | 3500                 | 10000              | 5000                         |
| 0.3                                                           | 4780                      | 8130               | 3350                 | 9560               | 4780                         |
| 0.35                                                          | 4600                      | 7820               | 3220                 | 9200               | 4600                         |
| 0.4                                                           | 4450                      | 7560               | 3110                 | 8900               | 4450                         |
| 0.45                                                          | 4320                      | 7340               | 3020                 | 8640               | 4320                         |
| 0.5                                                           | 4200                      | 7140               | 2940                 | 8400               | 4200                         |
| 0.6                                                           | 4020                      | 6830               | 2810                 | 8040               | 4020                         |
| 0.7                                                           | 3870                      | 6580               | 2710                 | 7740               | 3870                         |
| 0.8                                                           | 3740                      | 6360               | 2620                 | 7480               | 3740                         |
| 0.9                                                           | 3630                      | 6170               | 2540                 | 7260               | 3630                         |

| 3.5                                        | 2580                      | 4390               | 1810                 | 5160               | 2580                     |
| 4.0                                        | 2500                      | 4250               | 1750                 | 5000               | 2500                     |

In designing cast iron members to sustain stress of any character, the maximum allowable unit stress of any character shall be determined by the greatest thickness, exclusive of fillets, of the portion of the section carrying the stress being considered. In the main portion of a beam the thickness of the web or flange shall be used whichever is the greater. The thickness of the flange shall be considered either as the average depth of the outstanding portion or the breadth of flange outside to outside, whichever is less.

Cast Iron (Semi-Steel). See Item 502.

| Unfinished bolts and hand driven rivets .....                                                                                                                 | 6,000   | 12,000  |
| Bearing, pins, steel parts in contact, and shop driven rivets .....                                                                                           | 18,000  | 36,000  |
| Turned bolts and power driven field rivets .....                                                                                                              | 15,000  | 30,000  |
| Unfinished bolts and hand driven rivets .....                                                                                                                 | 12,000  | 24,000  |
| Rollers (lb. per lin. in.), where $d$ is the roller diameter in inches....                                                                                    | 450 $d$ | 900 $d$ |

In proportioning rivets, nominal diameters shall be used.

The effective bearing area of a pin, bolt or rivet is the diameter of the member multiplied by the thickness of the metal upon which the member bears.

In metal  $\frac{3}{8}$  in. thick and over, half the depth of countersink shall be omitted in calculating bearing area. In metal less than  $\frac{3}{8}$  in. thick, countersunk rivets shall not be assumed to carry stress.

Timber (used only for flooring and spiking strips), see Item 514 and Section 24.

502. **Cast Iron (Semi-Steel):** For the purposes covered by these specifications, castings of iron containing 18 per cent or more of steel are designated as semi-steel castings. For the corresponding thickness of section and nature of stress, the working stresses for semi-steel shall be 1.6 times those given in Table 2 for gray cast iron.

**503. Knife-edge Bearing Stresses:** The load per linear inch of knife-edge shall not exceed 5,000 pounds for high carbon steel and 6000 pounds for special alloy pivot steel.

**504. Concrete Bearing Stresses:** The stress to be allowed for bearing on concrete shall not exceed 300 pounds per square inch.

**505. Projecting Pivots—Formula for Stresses:** Where practicable, the pivots shall be supported their full length by integral parts of the lever. Where impracticable so to support the pivots, external bending moments shall be determined as follows:

Let  $M$  be the required bending moment in inch-pounds,

$L$ , the length in inches of the moment arm,

$W$ , the total lead in pounds on both ends of a pivot,

$D$ , the length in inches of bearing in the loop,

$T$ , the distance in inches between friction faces of the loop,

$B$ , the width in inches of the boss or sustaining member enveloping the pivot

Then

$$L = D/2 + (T - B) + 1/4"$$

And

$$M = WL/2$$

**506. Stringers, Floor Beams, and Floor Slabs:** When loads are, or may be applied to the scale platform from any direction, the following principles of design applicable to stringers, floor beams, and floor slabs shall be used. If, for any reason of design or installation, traffic over the scale is constrained to follow within definite limits a given direction, the stringer and floor beam sections, and the flooring, may be calculated to conform to the established traffic conditions.

**507. Shears and End Reactions in Stringers and Floor Beams:** In calculating end shears and end reactions in transverse floor beams and longitudinal beams and stringers, no lateral or longitudinal distribution of the vertical concentrated live loads shall be assumed.

**508. Bending Moment in Stringers:** In calculating bending moments in longitudinal beams or stringers, no longitudinal distribution of the loads shall be assumed. The lateral distribution shall be determined as follows:

(a) **Interior Stringers:** Interior stringers shall be proportioned for loads determined in accordance with the following table, except that when the limiting stringer spacings are exceeded, the stringer loads shall be determined by the reactions of live loads, assuming the flooring between stringers to act as a simple beam.

| <i>Kind of Floor</i>                                                      | <i>Fraction of Wheel Load<br/>to Each Stringer</i> | <i>Limiting Stringer<br/>Spacing in Feet</i> |
|---------------------------------------------------------------------------|----------------------------------------------------|----------------------------------------------|
| Plank .....                                                               | S/4.0                                              | 4.0                                          |
| Strip 4 in. in thickness or wood block on<br>4-inch plank sub-floor ..... | S/4.5                                              | 4.5                                          |
| Strip 6 in. or more in thickness.....                                     | S/5.0                                              | 5.0                                          |
| Concrete .....                                                            | S/6.0                                              | 6.0                                          |

$S$  = spacing of stringers in feet.

(b) **Outside Stringers:** The live load supported by outside stringers shall be the reaction of truck wheels, assuming the flooring to act as a simple beam between stringers.

(c) **Total Capacity of Stringers:** The combined load capacity of the beams in a panel shall not be less than the total live and dead load on the panel.

**509. Bending Moment in Floor Beams:** In calculating bending moments, no transverse distribution of loads shall be applied.

If longitudinal stringers are omitted and the floor is supported directly on the floor beams, the latter shall be proportioned for a fraction of the concentrated live loads as indicated in Item 508-(a), substituting "floor beams" for "stringers", except that when the limiting floor beam spacing is exceeded the floor beam loads shall be determined by the reactions of the loads, assuming the flooring between floor beams to act as a simple beam.

**510. Distribution of Wheel Loads on Concrete Slabs: Bending Moment:** In calculating bending stresses due to wheel loads on concrete slabs, no distribution in the direction of the span of the slab shall be assumed. In the direction perpendicular

to the span of the slab, the wheel load shall be considered as distributed uniformly over a width of slab which is termed the "effective width" and is obtained from the following formulas in which

$S$  is the span of slab in feet

$W$  is the width of tire in feet

$D$  is the distance in feet from the center of the near support to the center of wheel, and

$E$  is the "effective width" in feet for one wheel.

**Case I—Main reinforcement parallel to direction of traffic:**

$E = 0.7S + W$ , in which  $E$  shall have a maximum value of 7.0 feet.

When two wheels are so located on a transverse element of the slab that their effective widths overlap, the "effective width" for each wheel shall be  $\frac{1}{2}(E + C)$ , in which  $E$  is the value determined by the formula above and  $C$  is the distance between centers of wheels.

**Case II—Main reinforcement perpendicular to direction of traffic.**

$E = 0.7(2D + W)$ .

For this case, the bending moment on a strip of slab one foot in width shall be determined by placing the wheel loads in the position to produce the maximum bending, assuming no distribution; determining the effective width for each wheel; and assuming the load of each wheel on the one-foot strip to be the wheel load divided by its respective effective width.

The design assumption of Case II does not provide for the effect of loads near unsupported edges. Therefore, at locations where the continuity of the slab is broken, the edges of the slab shall be supported by diaphragms or other suitable means.

**511. Shear in Slabs:** Slabs designed for bending moment in accordance with the foregoing rules and for the wheel loads contemplated by these specifications may be considered adequate for shear without special reinforcement.

**512. Placing of Reinforcement:** The minimum clear distance between parallel bars shall be  $1\frac{1}{2}$  times the diameter of round bars, or  $1\frac{1}{2}$  times the diagonal of square bars. The maximum spacing shall be  $2\frac{1}{2}$  times the slab thickness. Bars parallel to the face of any member shall be imbedded a clear distance of not less than one inch from the face.

**513. Members Supporting Deck Overhang:** In calculating bending moments, and shears and reactions in members supporting the flooring outside the main girders, no lateral or longitudinal distribution of the vertical live loads shall be assumed.

**514. Floor Plank:** In motor truck and built-in scales when plank is used for platform covering, the thickness shall not be less than  $\frac{1}{8}$  the distance between spiking strips or members to which the plank is securely fastened, provided that in no instance shall the thickness be less than three inches. In motor truck scales, the width shall not be less than eight inches.

**515. Bearing Pressures: Soil and Rock:** The bearing areas of the foundation footings shall be such that the bearing pressure on the soil, under the worst condition of loading, will not exceed—

|                                              |                        |
|----------------------------------------------|------------------------|
| For fine sand or clay .....                  | 4,000 lb. per sq. ft.  |
| For coarse sand and gravel or hard clay..... | 6,000 lb. per sq. ft.  |
| For boulders or solid rock .....             | 20,000 lb. per sq. ft. |

If the soil has not a safe bearing capacity equal to that of fine sand or clay, its bearing capacity shall be increased by drainage, by adding a layer of gravel or broken stone, or by driving piles.

**516. Platform Overturning Moments:** In all scales, when calculating moments necessary to overturn or tip platforms, no distribution of vertical live loads shall be assumed. (See Item 2401.)

## 6. Particulars of Loading

**601. General:** All parts of scales shall be proportioned for the following loads and forces:

- (a) Dead load.
- (b) Live load.
- (c) Impact, or dynamic effect of live load.
- (d) Lateral forces.
- (e) Longitudinal forces.

**602. Dead Load:**

- (a) The dead load shall be considered in the design of motor truck scales. It shall be taken as the weight of all parts supported by the main lever load pivots.
- (b) The unit weights in Table 3 shall be used in computing dead load.

TABLE 3

## UNIT WEIGHTS OF MATERIAL FOR USE IN COMPUTING DEAD LOADS

| <i>Material</i>                       | <i>Weight per<br/>Cubic Foot</i> |
|---------------------------------------|----------------------------------|
| Steel—Use handbook values or .....    | 490                              |
| Cast Iron .....                       | 450                              |
| Timber, treated or untreated .....    | 60                               |
| Concrete, plain or reinforced .....   | 150                              |
| Pavement, other than wood block ..... | 150                              |

**603. Live Load:**

- (a) **Motor Truck Scales:** For the design of motor truck scales, the loading shall be assumed to be the sequence of moving, concentrated loads listed in Table 4.

TABLE 4

## SCHEDULE OF LIVE LOADS FOR MOTOR TRUCK SCALES

(a) For scales of 20,000 lb. nominal capacity with 16' by 8' platform, 30,000 lb. nominal capacity with 18' by 9' platform, and 60,000 lb. nominal capacity with 24' by 10' platform; one two-axle vehicle with wheelbase of 168 inches and wheels 72 inches apart, center to center; gross weight of vehicle equal to nominal capacity of scale, 90% of which is assumed to be concentrated on rear axle and 50% on one rear wheel of vehicle.

- (b) For all other sizes and capacities listed in Table I-(a):

| <i>Axle</i> | <i>Axle Load<br/>(wheels spaced 72 in. apart,<br/>center to center)<br/>(pounds)</i> | <i>Distance center to center<br/>of following axle<br/>(inches)</i> |
|-------------|--------------------------------------------------------------------------------------|---------------------------------------------------------------------|
| 1 .....     | 6,000                                                                                | 168                                                                 |
| 2 .....     | 16,000                                                                               | 40                                                                  |
| 3 .....     | 16,000                                                                               | 100                                                                 |
| 4 .....     | 16,000                                                                               | 40                                                                  |
| 5 .....     | 16,000                                                                               |                                                                     |

The combined live and dead loads to be used in design of parts shall be as listed in Table 5 (see also Item 604).

TABLE 5

## COMBINED LIVE AND DEAD LOADS TO BE USED IN THE DESIGN OF MOTOR TRUCK SCALES

(These loads are to be used for the design of parts made of materials for which the safe stresses given in Section 5 herein contain provision for impact.)

Note 1.—The "corner load" is the maximum reaction possible at any main load pivot.

Note 2.—The "end load" is the maximum reaction at the two main load pivots at the same end of the scale.

| <i>Platform Covering</i>                                         | <i>Corner Load<br/>(pounds)</i> | <i>End Load<br/>(pounds)</i> | <i>Total Load<br/>(pounds)</i> |
|------------------------------------------------------------------|---------------------------------|------------------------------|--------------------------------|
| (Scales of 24,000 lb. nominal capacity with 16' by 8' platform.) |                                 |                              |                                |
| Plank or Steel Plate .....                                       | 13,000                          | 24,900                       | 30,600                         |
| Concrete .....                                                   | 14,400                          | 27,600                       | 36,100                         |
| (Scales of 36,000 lb. nominal capacity with 18' by 9' platform.) |                                 |                              |                                |
| Plank or Steel Plate .....                                       | 21,200                          | 37,400                       | 45,100                         |
| Concrete .....                                                   | 23,000                          | 40,925                       | 52,200                         |

TABLE 5 (Continued)

| <i>Platform Covering</i>                                                        | <i>Corner Load<br/>(pounds)</i> | <i>End Load<br/>(pounds)</i> | <i>Total Load<br/>(pounds)</i> |
|---------------------------------------------------------------------------------|---------------------------------|------------------------------|--------------------------------|
| (Scales of 40,000 lb. to 60,000 lb. nominal capacity with 20' by 9' platform.)  |                                 |                              |                                |

| Concrete .....                                                                  | 25,700                          | 47,800                       | 83,100                         |
| (Scales of 40,000 lb. to 60,000 lb. nominal capacity with 20' by 10' platform.) |                                 |                              |                                |
| Plank or Steel Plate .....                                                      | 25,700                          | 43,300                       | 76,200                         |
| Concrete .....                                                                  | 27,900                          | 47,800                       | 84,900                         |
| (Scales of 40,000 lb. to 60,000 lb. nominal capacity with 22' by 9' platform.)  |                                 |                              |                                |
| Plank or Steel Plate .....                                                      | 25,400                          | 46,200                       | 76,500                         |
| Concrete .....                                                                  | 27,600                          | 50,500                       | 85,100                         |
| (Scales of 40,000 lb. to 60,000 lb. nominal capacity with 24' by 9' platform.)  |                                 |                              |                                |
| Plank or Steel Plate .....                                                      | 26,800                          | 49,100                       | 77,800                         |
| Concrete .....                                                                  | 29,100                          | 53,800                       | 87,100                         |
| (Scales of 40,000 lb. to 60,000 lb. nominal capacity with 24' by 10' platform.) |                                 |                              |                                |
| Plank or Steel Plate .....                                                      | 28,800                          | 49,700                       | 79,000                         |
| Concrete .....                                                                  | 31,500                          | 55,100                       | 89,800                         |
| (Scales of 60,000 lb. nominal capacity with 24' by 10' platform.)               |                                 |                              |                                |
| Plank or Steel Plate .....                                                      | 39,800                          | 64,000                       | 75,600                         |
| Concrete .....                                                                  | 42,300                          | 69,200                       | 85,800                         |
| (Scales of 60,000 lb. to 70,000 lb. nominal capacity with 34' by 10' platform.) |                                 |                              |                                |
| Plank or Steel Plate .....                                                      | 34,800                          | 61,000                       | 92,700                         |
| Concrete .....                                                                  | 38,500                          | 68,300                       | 107,400                        |

(b) **Built-in Scales:** In built-in scales the design shall provide for two live loads totaling the capacity of the scale, spaced apart equal to the shortest distance between two main lever load pivots, so located on the deck and so relatively proportioned as to cause the greatest stress in the member being designed. The maximum value of the greater of the two live loads shall be

$$L = 0.75 W - 0.25 D$$

and the minimum

$$L = 0.50 W$$

wherein  $W$  is the scale capacity

$D$  is the dead load.

(c) **Self-contained and Portable Scales:** In self-contained and portable scales, the design shall provide for a condition of live loading consisting of two equal loads totaling the scale capacity, spaced apart equal to the diagonal distance between main lever load pivots and so located as to cause greatest stress in the member being designed. Except in instances where, for some special reason, the design includes dead load features not regularly catalogued or comprised in the model of scale, the dead load may be neglected.

604. **Impact:** In the design of scales covered by these specifications, when stresses are used not greater than the "Working Stresses", Table 2, Section 5, herein, no increase need be made to vertical live loads, or need any other allowance be considered to provide for the effects commonly included under the general term "Impact".

#### 605. Lateral Forces.

(a) **Motor Truck and Built-in Scales:** The weigh-bridges of motor truck and built-in scales shall be designed for a lateral live load concentrated at the center of the span, equal to 20% of the capacity plus 100 pounds per foot of span.

(b) **Self-contained and Portable Scales:** In self-contained and portable scales, provision shall be made for the effect of a lateral force of 1000 pounds and 500 pounds, respectively, acting in the plane of the deck and in a vertical plane through the transverse center line.

#### 606. Longitudinal Forces:

(a) **Motor Truck and Built-in Scales:** In motor truck and built-in scales, provision shall be made for the effect of a longitudinal force of 10% of the capacity of the scale acting four feet above the plane of the deck and in a vertical plane through the longitudinal center line.

(b) **Self-contained and Portable Scales:** In self-contained and portable scales, provision shall be made for the effect of a longitudinal force of 1000 pounds and 500 pounds, respectively, acting in the plane of the platform and in a plane through the longitudinal center line.

## 7. Scale Levers

701. **Type:** Levers with truss rods will not be permitted.

702. **Qualities of Castings:** Cast pieces used for levers shall not be warped. They shall be clean, smooth, uniform, and free from blisters, blowholes and shrinkage cracks.

703. **Machined Ways for Nose Irons:** In motor truck scales, levers that are to be equipped with nose irons shall have those portions of the lever ends receiving them machined for the full distance over which the nose irons are to move.

704. **Nose Iron Guides:** The guides for all nose irons shall be such that when one is moved for the purpose of adjustment, the pivot will be held parallel to its original position.

705. **Leveling Lugs:** In motor truck scales and built-in scales of the straight lever type, each lever shall be provided with leveling lugs for longitudinal alinement; for torsion levers, leveling lugs shall be provided on the pipe or torsion member for transverse alinement, and on the extension arm for longitudinal alinement. Each pair of lugs shall be spaced 11 inches. The leveling surfaces of each pair of lugs shall be finished to a common plane parallel to the plane established by the knife-edges of the end pivots.

706. **Marking of Levers:** In motor truck scales, figures denoting the ratio of each lever shall be cast or otherwise permanently marked on the lever.

## 8. Pivots and Bearings

801. **Material:** The material used for pivots and bearings in scales covered by these specifications shall be either—

(a) Special alloy pivot steel (S.A.E. No. 6195), hardened to Rockwell C scale not less than 58, or

(b) Carbon steel (S.A.E. No. 1095), hardened to Rockwell C scale not less than 60.

802. **Design:** In motor truck scales and built-in scales, all pivots shall be so designed and manufactured that the included angle of the sides forming the knife-edge will not exceed 90 degrees, and the offset of the knife-edge as referred to the center line of the pivot will not exceed 10% of the width of the pivot for "machined in" pivots and 15% of the width of the pivot for "cast in" pivots.

803. **Fastening:** All pivots shall be firmly fastened in position without swedging or caulking.

804. **Continuous Contact:** All pivots shall be so mounted as to secure equal and continuous contact of the knife-edges with their respective bearings for the full length of the parts designed to be in contact; in loop bearings, the knife-edges shall project slightly beyond the bearings in the loops.

805. **Position:** In any lever, pivots shall be so mounted that—

(a) Each knife-edge will be maintained in a horizontal plane under any load within the capacity of the scale.

(b) A plane bisecting the angle of a knife-edge will be perpendicular to the plane through the knife-edges of the end pivots.

(c) In motor truck and built-in scales, the actual distance between the end knife-edges of any lever does not differ from the nominal distance by more than 1/64 inch per foot.

806. **Support for Projecting Pivots:** The reinforcing on the levers to support projecting pivots shall be tapered off to prevent accumulation of dirt next to the pivots and to provide proper clearances.

807. **Design of Bearings:** Bearings and the parts supporting or containing them shall be so applied to the mechanism that permissible movement of the platform will not displace the line of contact between any bearing and the opposing pivot.

808. **Mounting of Bearing Steels:** All bearing steels of the same nominal dimensions or parts identification shall be interchangeable or mounted in interchange-

able bearing blocks. The interchangeable part shall be securely mounted in the part containing it.

**809. Finish of Bearing Steels:** The bearing surfaces shall be brought to a smooth, true and accurate finish to insure continuity of contact with opposing pivots.

## 9. Nose Irons

**901. Design and Fastening:** Nose irons shall be constructed so that they may be fastened in proper position by means of U. S. Standard screws or bolts, or other equally effective mechanical device.

**(a) Design of Fastening:** The device for clamping the nose irons in position shall be of such design that indentations in the lever will not be made, and for motor truck scales and built-in scales it shall be independent of any means provided for adjustment.

**(b) Direction of Fastening:** The devices for fastening nose irons shall be so designed that loads applied to the scale will not cause tension in the fastening bolts. For motor truck and built-in scales, clamping devices shall hold nose irons against levers in the same direction they would be forced by the load, and shall be such that any nose iron will remain in place when the clamping device is released.

**(c) Control of Nose Iron Movement:** The movement of the nose irons shall be controlled by means of adjusting screws of U. S. Standard size and thread. For motor truck scales, these screws shall be made of non-corrosive material.

**902. Marking of Position:** The position of each nose iron as determined by the factory adjustment shall be accurately, clearly and permanently indicated by a well-defined mark on the lever and nose iron, which shall meet on a common line.

**903. Finish and Pivot Mounting:** Those surfaces of the nose iron intended to come into slidable contact with the levers shall be made true so as to secure an accurate fit of the nose irons on or in the levers. Each nose iron shall be of such design that when adjustments are made the knife-edge will be held parallel to its original position.

## 10. Loops and Connections

**1001. Design Proportion:** Loops which form bearings for projecting pivots may be of any type, provided the clearance between the enclosed pivots and the body of the loop is at least one-fourth inch.

**1002. Length:** All loops of like connections shall be of the same length.

**1003. Vertical Adjustment:** Means for vertical adjustment shall be provided between the lever system and the beam, which will permit independent leveling of the shelf lever when one is used. When no shelf lever is used, the connection to the beam shall be adjustable. Screw adjustments shall be provided with lock nuts or equivalent device.

## 11. Lever Fulcrum Stands

**1101. Qualities of Castings:** Castings for lever stands shall be clean, smooth, uniform, and free from blisters, blowholes and shrinkage cracks.

**1102. Position on Bases:** The upright portion of any stand shall be so placed on its base that the resultant line of forces applied through the bearing carried by the stand falls within the middle third of the length and width of the base.

**1103. Bases for Lever Stands:** The base of any lever stand shall be smooth, or shall be finished in any suitable manner true within a tolerance of  $\frac{3}{32}$  inch to a plane perpendicular to a vertical line through the center of the knife-edge bearing carried by the upright portion of the stand.

**1104. Finish of Tops of Stands:** The top of any lever stand for receiving a bearing steel, cap or block shall be finished to a tolerance of  $\frac{3}{32}$  inch of a plane parallel to the base.

**1105. Anchor Bolt Holes:** For built-in scales of the A-lever type, one anchor bolt hole  $1\frac{1}{2}$  inches in diameter shall be provided in the base of each stand. In all other scales, two or more anchor bolt holes,  $1\frac{1}{2}$  inches in diameter, shall be provided in the base of each stand unless other equally effective means for anchorage is provided.

## 12. Checks

1201. **Type:** The weigh-bridges, or platforms, of all scales shall be equipped with devices which effectively restrict motion in any horizontal direction, so designed and constructed as to withstand adequately the horizontal forces prescribed in Items 605 and 606. For motor truck and built-in scales, if checks of either the rod or bumper type are used, they shall be adjustable.

## 13. Weigh-Beams and Accessories

1301. **Capacity to be Marked:** The capacity of the scale as defined in Item 301-(a) shall be explicitly and conspicuously marked on or near the beam.

1302. **Requirement for Nominal Capacity:** The nominal capacity as defined in Item 301-(b) shall not exceed the scale capacity.

### 1303. Type of Beam:

(a) **Motor Truck Scales:** Full-capacity beams shall be used with motor truck scales. The arrangement may be such that the entire tare weight can be set up independently of the main beam, or the beam bar used for the determination of the net lading, provided (1) Tare beams or bars shall not be used with registering beams; (2) the sum of the weights determinable on the tare weight and net weight or main beams shall not conflict with the definitions and requirement in Items 301 and 1302; and (3) when tare beams are furnished, the graduations of the principal and fractional bars shall comply with the specifications given for the main beam. (See Item 1306)

(b) **Other than Motor Truck Scales:** At the option of the purchaser, a full-capacity beam with tare weight bar, or double or single beam with counterpoise weights shall be furnished with built-in, self-contained and portable scales.

1304. **Ratio:** A pivot and loop shall be provided at the beam tip. For other than motor truck scales, the ratio at the beam tip pivot shall be—

|                                 |             |
|---------------------------------|-------------|
| For built-in scales .....       | 500 or 1000 |
| For self-contained scales ..... | 200 or 300  |
| For portable scales .....       | 100         |

For all scales, the ratio to the beam butt pivot shall be plainly and permanently stamped on the beam.

1305. **Poise Stop:** In all scales, each beam bar shall be provided with a stop to prevent movement of the beam poise back of the zero notch or graduation.

1306. **Notches:** On main beams the notches shall not be spaced closer than six to the inch. Each notch shall be so made that when the pawl rests in it, a line projected from the center of the side of the notch nearer the zero graduation to the axis about which the pawl stem rotates will be perpendicular to that side of the notch.

(a) In motor truck scales, the value of each notch on the main beam shall be 1,000 pounds.

1307. **Pawl or Latch:** The tip of the pawl or latch shall be of the same width as the notches of the beam and shall be rounded so that a small amount of foreign material in the bottom of the notch will not prevent the poise from assuming its correct position when the pawl is dropped in the notch.

1308. **Projections or Recesses:** Poises shall be designed with the object of reducing to a minimum the number of projections and recesses that will retain foreign material.

1309. **Poise Bearings:** Each poise shall be constructed to move along its beam without side play. In full-capacity beams, the main poises shall be equipped with roller or other form of frictionless bearing.

1310. **Fractional Beams:** The fractional poise on a full-capacity registering beam shall be constructed to stop positively at each graduation and to prevent movement beyond the last graduation. In motor truck scales, the last registration of the fractional poise shall be 990 pounds, and in built-in and self-contained scales, 98 pounds or 95 pounds.

1311. **Operating Lever:** On registering beams, a substantial type of hand grip shall be provided to facilitate the registration of the weight. The natural operation of the registering mechanism shall not cause lateral displacement of the beam.

1312. **Receptacle for Weight Ticket:** On registering beams, means shall be provided to prevent placing the weight ticket in its receptacle in any position in which a weight can be registered different from that represented by the poise setting.

1313. **Balance Ball:** For motor truck scales, the position of the balance ball shall be vertically adjustable. Longitudinal movement shall be controlled by means of a self-contained hand-operated screw or other device which will not require the ball to

be rotated in making adjustments. Means for locking the ball in position shall be provided.

**1314. Poises and Counterpoise Weights:**

(a) **Material:** Counterpoise weights and the exterior shell of poises shall be made of non-corrosive alloys, steel, iron, brass, or any other metal or alloy of metals not softer than brass. Poises shall have no metal softer than brass making contact with the beam.

(b) **Corrosion Protection:** Weights made of corrosive material, such as cast iron or steel, shall be protected from corrosion by the application of a durable chemical coating.

(c) **Surface and Form:** Weights shall be smooth, without sharp points or corners, and of such form that the minimum surface consistent with convenience of use will be exposed to wear or corrosion.

(d) **Adjusting Cavities:** All cavities for adjusting material shall be formed in the top or sides of counterpoise weights, and shall be of such form that the adjusting material will be permanently and securely retained. The adjusting material shall not project beyond the surface of the weight and, if in the top of the weight, the material closing the cavity shall be not more than 0.04 inch below the surface.

(e) **Movable Parts:** All movable elements forming a part of a poise shall be so constructed as not to be detachable without manifest mutilation of the poise. Set screws, if used to secure a poise at any point on a beam, shall not be removable.

(f) **Marking:** All counterpoise weights shall be clearly marked with their nominal weight, i.e., 1 lb., 2 lb., etc., and also with the value they represent when used upon the scale for which they are intended.

(g) **Sealing:** After the weights are adjusted to their proper value, all caps or plugs closing adjusting cavities shall receive the impression of a seal, appropriate in character or design, to attest the factory adjustment, if made at the factory of the manufacturer; or, if readjusted elsewhere, the seal shall be such as to indicate where the adjustment was made.

(h) **Counterbalance Weights:** If counterbalance weights are to be used, the lower end of the hanger stem shall be threaded; a cup for the loose balancing material shall be screwed to the lower end of the stem; and each additional weight shall be provided with an elongated hole in the center through which the hanger stem may pass. No slotted counterbalance weights are to be used. When no counterbalance weights are necessary on top of the counterbalance cup, the cavity shall be closed by a cover secured in a positive manner. No counterbalance weights shall be used in any place in the scale except at the beam.

(i) **Tolerances:** The manufacturer's tolerances, or the tolerances to be allowed on new counterpoise weights and the tolerances which shall apply on readjusting the weights shall be no greater than the values in the following table.

TABLE 6

**TOLERANCES ON NEW OR NEWLY ADJUSTED COUNTERPOISE WEIGHTS  
FOR MULTIPLYING LEVER SCALES**

(Avoirdupois System)

| <i>Weight<br/>(pounds)</i> | <i>Ratio 100:1 and<br/>less than 1000:1<br/>(grains)</i> | <i>Ratio 1000:1<br/>and over<br/>(grains)</i> |
|----------------------------|----------------------------------------------------------|-----------------------------------------------|
| 15 .....                   | 8.0                                                      | 4.0                                           |
| 10 .....                   | 8.0                                                      | 4.0                                           |
| 8 .....                    | 6.0                                                      | 3.0                                           |
| 5 .....                    | 6.0                                                      | 3.0                                           |
| 4 .....                    | 4.0                                                      | 2.0                                           |
| 3 .....                    | 4.0                                                      | 2.0                                           |
| 2 .....                    | 3.0                                                      | 1.5                                           |
| 1 .....                    | 2.0                                                      | 1.0                                           |
| <i>(ounces)</i>            |                                                          |                                               |
| 10 .....                   | 2.0                                                      | 1.0                                           |
| 8 .....                    | 1.0                                                      | 0.5                                           |
| 5 .....                    | 1.0                                                      | 0.5                                           |
| 4 .....                    | 1.0                                                      | 0.5                                           |

**1315. Identification of Parts:** A serial number shall be stamped on the front of each complete beam.

**1316. Type Figures:** On type registering beams, type figures shall be made of material sufficiently hard that, under the designed conditions of use, the figures will not become battered or defaced. The figures shall be plain and raised sufficiently high to insure a clear impression upon the weight ticket or tape. They shall be so attached that they cannot become loosened or detached without a positive indication that the beam is out of order.

**1317. Beam Fulcrum Stands:** The upright portion of any beam fulcrum stand shall be so placed on the base that for any position of the beam in the normal weighing operation the line of resultant force through the fulcrum knife-edge will pass through the middle third of the length and width of the base.

(a) **Motor Truck Scales:** For motor truck scales the beam shall not be suspended. It shall be supported on a stand provided with compensating bearings.

**1318. Trig Loops:**

(a) **Material:** Trigs made of non-magnetic material shall be provided with beams made of magnetic material.

(b) **Play of the Beam:** The vertical movement of the beam in the trig loop shall not be less than that given in Table 7.

TABLE 7

MINIMUM VERTICAL MOTION OF WEIGH-BEAMS IN TRIG LOOPS

| Length of Beam<br>(Distance from fulcrum to trig loop) | Minimum Vertical Motion<br>in Trig Loop |
|--------------------------------------------------------|-----------------------------------------|
| Under 12 inches                                        | 0.4 inch                                |
| Over 12 inches, including 20 inches                    | 0.5 "                                   |
| Over 20 inches, including 40 inches                    | 0.7 "                                   |
| Over 40 inches                                         | 0.9 "                                   |

**1319. Beam Support:** In portable scales the pillar supporting the beam shall be rigid. In other scales the beam fulcrum stand and trig loop stand shall be securely fastened to a shelf sufficiently strong and so supported that it will not deflect to an extent affecting the weighing performance.

**14. Anti-Friction Points and Plates**

1401. Anti-friction contacts shall be used to limit longitudinal displacement between knife-edges or pivots and their bearings. They shall be smooth and so designed as to provide contact at a point on the line of the knife-edge of pivots. For motor truck and built-in scales they shall be of hardened steel.

**15. Clearances**

1501. The clearance around and between the fixed and live parts of the lever system of motor truck scales shall be at least three-fourths ( $\frac{3}{4}$ ) of an inch, and for built-in and self-contained scales the clearance shall be not less than three-eighths ( $\frac{3}{8}$ ) of an inch. The total clearance between anti-friction points on levers and stands shall be not less than one-sixteenth ( $\frac{1}{16}$ ) of an inch nor greater than one-eighth ( $\frac{1}{8}$ ) of an inch.

**16. Factory Adjustments**

1601. **Levers:** The design, workmanship and factory adjustment of the levers and beam shall be such that the proper ratio of the lever arms will be maintained.

**17. Interchangeability**

1701. Like parts of all like motor truck and built-in scales of the same design and manufacture shall be interchangeable unless otherwise herein specified. The scale drawings and the parts of the scale shall be marked to indicate the proper positions of the parts in the scale.

**18. Sensibility Reciprocal (SR)**

1801. **Definition:** The sensibility reciprocal is the weight required to be added to or removed from the scale platform to turn the beam from a position of equilibrium in the center of the trig loop to a position of equilibrium at either limit of its travel.

## 19. Tolerances

**1901. Errors:** The tolerance on errors in excess or deficiency for motor truck, built-in, self-contained and portable scales when tested upon the site of use and before being accepted as satisfactory weighing machines, shall be 0.10% of the applied load consisting of test weights of known value; provided (1) the tolerance shall not be less than one-half the minimal beam graduation on the scale being tested; and (2) a purchaser may by stipulation in the purchase order require scales on the same condition of test to meet tolerances not less than one-half, respectively, of the tolerances given above before accepting delivery.

**1902. Sensibility Reciprocal:** For the same classes of scales and the same conditions of test stipulated in Item 1901, the sensibility reciprocal shall not exceed the value of the minimal beam graduation.

## 20. Location and Elevation

**2001. Location:** Motor truck, built-in and self-contained scales shall be so located that an adequate foundation and a straight approach in line with the scale platform and of a length in excess of that of the longest vehicle to be weighed can be provided.

**2002. Elevation:** The scale platform shall be raised to such an elevation that the drainage of surface water will be away from it and, unless space will not permit it, the approaches shall be level, or nearly level, and paved for a length equal to that of the scale platform.

## 21. Foundations

**2101. Material:** Scale foundations resting upon or extending into the ground shall be constructed of concrete. (See Item 515).

**2102. Dimensions of Pit:** For motor truck and built-in scales, the size of the pit shall be such as to give a vertical clearance between the scale levers and the finished floor of the pit of not less than two (2) feet, and a horizontal clearance between the face of the pit walls and the scale parts below the platform, or below the weigh-bridge girders, if any, and above the bases of the stands, of not less than four (4) inches for motor truck scales and 1½ inches for built-in scales.

**2103. Walls of Pit:** The walls of the pit shall have a thickness at the top of not less than twelve (12) inches for motor truck scales, and not less than eight (8) inches for built-in scales.

**2104. Waterproofing:** When necessary, the pit shall be waterproofed.

**2105. Wall Batter:** All wall surfaces next to earth subject to freezing shall be constructed with a uniform batter of not less than one (1) inch to the foot, and as much more as necessary to permit the heaving of adjacent ground by frost action without disturbing the walls.

**2106. Pit Floors and Lever Stand Piers:** The concrete piers supporting the lever stands shall be not less than nine (9) inches deep, but shall in any case be carried to proper foundation. Their tops shall be above the floor of the pit a distance sufficient to prevent the accumulation of water under the bases of the stands, and they shall be finished to exact level and elevation to receive the lever stands. The floor of the pit may be designed as a mat footing of concrete, or as a simple floor not less than four (4) inches thick. The pit floor shall, in all cases, be smooth, with a pitch to a common point of drainage, and free from pockets in which water will stand.

**2107. Anchor Bolts:** Anchor bolts, not less than seven-eighths ( $\frac{7}{8}$ ) inch in diameter, threaded and with nuts and washers, shall be provided in the foundations for lever stands to match the bolt holes provided for securing the stands, and they shall extend into the concrete not less than eight (8) inches.

**2108. Anchorage for Floating Levers:** A floating lever, that is, one exerting an upward pull at its fulcrum, shall be anchored to the foundation to resist not less than twice the upward pull produced at the fulcrum pivot by a capacity load on the scale.

## 22. Scale Beam House or Box

**2201. Scale Beam House or Box:** When the scale is not located in a building, the scale beam shall be adequately protected from the weather by being enclosed in a house or box. When a scale is located in a building, it shall, when necessary, be similarly protected from injury.

2202. **Design:** The minimum inside width of the scale house shall be four (4) feet, and the minimum length shall be sufficient to allow the installation therein of the beam shelf and beam. It shall be provided with windows of such size and location as will give the weigher, when weighing, a clear and unobstructed view of the scale platform and approaches. The windows shall be glazed with clear glass or clear wire glass. If the beam is required to be boxed, the box shall be of such size as to suitably enclose the beam shelf and beam. It shall be provided with a hinged door, or doors, of such size and in such location as to give the weigher clear and unobstructed access to the beam.

2203. **Clearance:** A clearance of not less than one (1) inch shall be provided between the inside of the scale house and the beam supports and shelf. The clearance between the edge of the platform and weighbeam pillar, beam box or scale house shall be sufficient to permit the normal functions of weighing the widest loads required to be handled.

## 23. Installation

2301. **Fastening of Stands:** After alining the stands, the anchor bolt holes in the castings shall be filled with cement, sulphur or other suitable material, and the anchor bolt nuts brought down tight.

2302. **Alinement:** All levers shall be level and connections plumb throughout the scale.

## 24. Platforms

2401. **Security Against Tipping:** All scale platforms shall be proportioned so that, for any possible application of the loads specified for different classes of scales in Section 6, no tipping can occur. (See Item 516.)

2402. **Timber:** In all scale platforms, timber shall not be used for floor beams, stringers, or in any members, except floor covering, required to take shearing or compressive stress perpendicular to the grain, or stress in transverse bending. Timber may be used for floor covering and, as required, for spiking or fastening strips for the floor covering. (See Items 514 and 2409.)

2403. **Weigh-Bridges:** For motor truck and built-in scales, weigh-bridge girders, floor beams and stringers shall be made of steel conforming to American Railway Engineering Association Specifications for Steel Highway Bridges, Sections II and III.

### 2404. Sections and Strength:

(a) Weigh-bridge members shall be designed in accordance with Sections XIV and XV of the American Railway Engineering Association Specifications for Steel Highway Bridges, except as the permissible working stresses and loading conditions are modified by Sections 5 and 6 herein.

(b) **Motor Truck Scales:** In motor truck scale weigh-bridges, the section moduli of main girders shall be shown in Table 8.

TABLE 8

### SECTION MODULI OF MAIN WEIGH-BRIDGE GIRDERS FOR MOTOR TRUCK SCALES

(These values contain provision for impact)

| Capacity and Platform Size |             | Section Modulus, One Girder  |               |
|----------------------------|-------------|------------------------------|---------------|
|                            |             | Plank or<br>Steel Plate Deck | Concrete Deck |
| 24,000 lb.                 | 16' by 8'   | 38.0                         | 40.3          |
| 36,000 lb.                 | 18' by 9'   | 64.6                         | 68.1          |
| over )                     | (20' by 9'  | 68.7                         | 73.1          |
| 36,000 lb.)                | (20' by 10' | 69.3                         | 74.1          |
| but less than)             | (22' by 9'  | 81.4                         | 86.8          |
| 60,000 lb.)                | (24' by 9'  | 98.6                         | 104.9         |
|                            | (24' by 10' | 99.5                         | 107.1         |
| 60,000 lb.)                | 24' by 10'  | 178.4                        | 185.7         |
| 60,000 lb.)                | 34' by 10'  | 189.7                        | 204.4         |
| to 70,000 lb.)             |             |                              |               |

### 2405. Bracing:

(a) **Built-in Scales:** Weigh-bridges for built-in scales ordinarily will require no bracing other than floor beams and corner plates.

(b) **Motor Truck Scales:** If the floor beams are mounted above the main girders, weigh-bridges of motor truck scales with solid floor construction or with transverse floor beams on 36-inch centers or less will require no lateral bracing. Otherwise bracing shall be designed for the forces in Item 605—(a). The internal bracing members shall not be less than  $3'' \times 3'' \times \frac{1}{4}''$  angles.

(c) **Cross Frames:** Motor truck scale weigh-bridges with the floor beams mounted above the main girders shall be provided with end cross frames and at least one intermediate cross frame. If the floor beams are internally framed and the weigh-bridge otherwise adequately braced, the end and intermediate cross frames may be omitted.

**2406. Fabrication and Assembly:**

(a) **Motor Truck Scales:** The weigh-bridges for motor truck scales shall, when practicable, be assembled and riveted up complete in the shop. When field assembly is necessary, the parts shall be properly assembled in the shop and match-marked. Connecting holes shall be reamed to fit.

(b) **Built-in Scales:** The weigh-bridges for built-in scales shall be assembled and riveted, or bolted up in the shop under proper inspection. When delivered, they shall be square and the surfaces receiving the platform bearings shall be parallel.

**2407. Platform Bearings:** In motor truck scales and built-in scales, the tops of platform bearings contacting the weigh-bridge girders shall be finished to within  $\frac{1}{32}$  inch of a true plane. These tops shall be provided with bolt holes of sufficiently large diameter to allow for the transverse and longitudinal adjustment necessary to secure proper alinement of parts.

**2408. Deck:** The deck or floor shall be designed so that, without exceeding the permissible stresses, it will support and distribute the capacity load and incidental forces when applied as described in Section 6, and so as to produce the maximum stress in any part of the floor.

**2409. Flooring:** The flooring shall be of such material as will resist wear, will under all weather conditions provide traction to power-driven vehicles, and which can be waterproofed. If timber is used, its quality must be at least No. 1 Common dimension, treated with a preservative.

**2410. Self-contained and Portable Scales:** The platforms of self-contained and portable scales shall be entirely of metal, or a metal frame with a hardwood center panel, and shall be so designed that, without exceeding the permissible stresses, the loads and forces prescribed in Section 6, when so applied as to produce maximum stress, can be sustained.

**25. Light, Drainage and Ventilation**

**2501. Light:** Proper lighting of the scale weighing beam and scale platform shall be provided.

**2502. Drainage:** Adequate drainage for scale pits shall be provided and maintained.

**2503. Ventilation:** All scale pits shall be ventilated to meet the needs of each particular case, the object being to minimize the amount of moisture in the air in the pit and so to retard rusting of scale parts and structural steel.

**26. Entrance to Scale Pit**

**2601. Location:** For built-in scales, the entrance to the scale pit for inspection purposes shall be through the platform of the scale, foundation wall, or the neck of the scale pit, and shall be closed by a suitable door; for motor truck scales, the entrance to the scale pit shall be through the foundation wall or neck of the pit.

**27. Protection from Corrosion**

**2701. Shop Painting:** When no shop inspection is provided, or after shop inspection when it is provided, all parts of the mechanism and structural steel of motor truck and built-in scales shall be given one coat of red lead and linseed oil, and all parts of the mechanism of self-contained and portable scales shall be given two coats, and the inside of the platform and the frame one coat of paint. In riveted work, surfaces coming in contact shall be given one coat of red lead paint before being riveted together. All parts of motor truck and built-in scales which are inaccessible after erection shall be given a second shop coat of red lead paint.

**2702. Field Painting:** All parts of the scale mechanism and structural steel of motor truck and built-in scales shall be cleaned and painted with one coat (and preferably two coats) of approved paint in the field before installation.

## SUPPLEMENT TO REPORT OF COMMITTEE XIV—YARDS AND TERMINALS

MODIFICATIONS TO APPENDIX D, REPORT OF SUB-COMMITTEE  
5, SCALES USED IN RAILWAY SERVICE (BULLETIN 361,  
NOVEMBER, 1933)

---

*To the American Railway Engineering Association:*

PROPOSED SPECIFICATIONS FOR THE MANUFACTURE AND IN-  
STALLATION OF MOTOR TRUCK, BUILT-IN, SELF-CONTAINED  
AND PORTABLE SCALES FOR RAILWAY SERVICE (PAGE 447)

The Scale Sub-Committee was unable to complete this year the assignment of revising the Specifications for Motor Truck, Built-in, Self-Contained and Portable Scales for Railway Service now contained in the 1929 Manual, page 1034. Nevertheless, developments in the trade seem to require that the work thus far completed be introduced to an active status. For that reason we propose to withdraw this year from the Manual the subject material there, and to publish the work thus far completed as "Information." Since the conclusion to do that was reached opportunity to press the work farther was found. In order that the "Information" formally published might contain the advantage of the latest developments, we offer them herewith as a Supplemental Report with the intent they shall be published in the current Proceedings either suitably incorporated in the main report, or as an appendix to it.

The modifications apply to Appendix D, page 447, Bulletin 361, and are to be inserted at the places indicated.

### Section 5—Page 449

#### Design Data—Working Stresses and Formulas

Change Item 501, Table 2, thus: Follow the table to the item, Cast-Iron (Semi-Steel), change to Cast Iron (Semi-Steel, and Other Alloys). See Item 502.  
Set to the end of the table.

Change Item 502, Page 450, thus:

#### 502. Cast Iron (Semi-Steel, and Other Alloys).

(a) Semi-Steel: For the purposes covered by these specifications, castings, or iron containing 18 per cent or more of steel are designated as semi-steel castings. For the corresponding thickness of section and nature of stress, the working stresses for the semi-steel shall be 1.6 times those given in Table 2 for grey cast iron.

(b) Other Alloys: For other alloys intended or represented to be "high strength" cast iron, unit working stresses other than those given in Table 2 may be used, provided these are acceptable to the purchaser and have been established according to test routine followed or prescribed by the American Society for Testing Materials. In all instances, the purchaser, if he requests, shall be furnished with sufficient data to enable him to determine the physical properties of the particular "high strength" material proposed to be used.

## Section 6—Page 452

## Particulars of Loading

Change Item 602, Page 453, thus:

## 602. Dead Load.

(a) Unless provision is otherwise made in these specifications, the dead load shall be considered in the design of scales. The dead load shall be considered as the weight of all parts of the scale structure supported by the main lever load pivots and balanced out for the zero beam reading.

(b) The unit weights in Table 3 shall be used in computing dead load.  
Continue with Table 3.

Change Table 4, Page 453, thus:

## SCHEDULE OF LIVE LOADS FOR MOTOR TRUCK SCALES

(a) For scales of 24,000 lb. nominal capacity with 16 ft. by 8 ft. platform, 36,000 lb. nominal capacity with 18 ft. by 9 ft. platform, etc. Set the rest of the table.

Change Table 5, Item 603, Page 453, thus:

TABLE 5

COMBINED LIVE AND DEAD LOADS TO BE USED IN THE DESIGN OF  
MOTOR TRUCK SCALES

NOTE 1—These loads are to be used for the design of parts made of materials for which the safe stresses are given in Section 5.

NOTE 2—The "corner load" is the maximum reaction at any main load pivot.

NOTE 3—The "end load" is the maximum reaction at the two main load pivots at the same end of the scale.

NOTE 4—For definition of "nominal capacity," see Item 301-(b).

| <i>Nominal<br/>Capacity<br/>(Pounds)</i> | <i>Platform<br/>Size<br/>(Feet)</i> | <i>Corner<br/>Load<br/>(Pounds)</i> | <i>End<br/>Load<br/>(Pounds)</i> | <i>Total<br/>Load<br/>(Pounds)</i> |
|------------------------------------------|-------------------------------------|-------------------------------------|----------------------------------|------------------------------------|
| 24,000                                   | 16 by 8                             | 14,400                              | 27,600                           | 36,100                             |
| 36,000                                   | 18 by 9                             | 23,000                              | 40,900                           | 52,200                             |
| 60,000                                   | 24 by 10                            | 42,300                              | 69,200                           | 85,800                             |

The values just given are for the special scales designed particularly for the two axled vehicle described in Table 4, under the subhead (a).

For regular service and for other conditions of loading, not more severe than those described in Table 4, under the subhead (b), the following values apply:

|                       |          |        |        |         |
|-----------------------|----------|--------|--------|---------|
| Less than 60,000..... | 20 by 9  | 25,700 | 47,800 | 83,100  |
| Same .....            | 20 by 10 | 27,900 | 48,900 | 84,900  |
| Same .....            | 22 by 9  | 27,600 | 50,500 | 85,100  |
| Same .....            | 24 by 9  | 29,100 | 53,800 | 87,100  |
| Same .....            | 24 by 10 | 31,500 | 55,100 | 89,800  |
| 60,000 to 70,000..... | 34 by 10 | 38,500 | 68,300 | 107,400 |

Change Item 606, Page 454, thus:

### Longitudinal Forces

#### 606. Longitudinal Forces.

(a) **Motor Truck and Built-in Scales:** In motor truck and built-in scales, provision shall be made for the effect of a longitudinal force of 10 per cent of the capacity of the scale acting in the plane of the platform and in a vertical plane through the longitudinal center line.

### Section 7—Scale Levers

Change Item 701, Page 455, thus:

701. **Limitation of Type:** Truss rods shall not be used in parts of the lever system except to stiffen levers laterally, or to prevent whipping and vibration due to impacting loads. Truss rods designed as parts of a lever structure to support vertically applied loads will not be permitted.

### Section 13—Weighbeams and Accessories

Change Item 1313, thus:

1313. **Balance Ball:** For motor truck scales the position of the balance ball shall be vertically adjustable. Unless otherwise required by law or regulation, longitudinal movement shall be controlled by means of a self-contained hand-operated screw or other device which will not require the ball to be rotated in making adjustments. Means for locking the ball in position shall be provided.

Change Section 24—Platforms, thus:

Stet to Table 8, then change

TABLE 8

### SECTION MODULI OF MAIN WEIGHBRIDGE GIRDERS FOR MOTOR TRUCK SCALES

(These Values Contain Provision for Impact)

| <i>Nominal Capacity<br/>(Pounds)</i> | <i>Platform Size<br/>(Feet)</i> | <i>Section Modulus<br/>One Girder</i> |
|--------------------------------------|---------------------------------|---------------------------------------|
| <b>SPECIAL SERIES</b>                |                                 |                                       |
| 24,000                               | 16 by 8                         | 40.3                                  |
| 36,000                               | 18 by 9                         | 68.1                                  |
| 60,000                               | 24 by 10                        | 185.7                                 |
| <b>REGULAR SERIES</b>                |                                 |                                       |
| Less than 60,000                     | 20 by 9                         | 73.1                                  |
| Same                                 | 20 by 10                        | 74.1                                  |
| Same                                 | 22 by 9                         | 86.8                                  |
| Same                                 | 24 by 9                         | 104.9                                 |
| Same                                 | 24 by 10                        | 107.1                                 |
| 60,000 to 70,000                     | 34 by 10                        | 204.4                                 |

Stet the rest of the section.

**Section 12—Checks—Page 457**

Item 1201. **Type:** The weighbridges or platforms of all scales shall be equipped with devices which effectively restrict motion in any horizontal direction sufficiently to prevent contact between the platform and foundation wall or coping, so designed, as to withstand the horizontal forces prescribed in items 605 and 606. For motor truck and built-in scales, if checks either of the rod or bumper type are used, they shall be adjustable.

Respectfully submitted,

THE COMMITTEE ON YARDS AND TERMINALS,

M. J. J. HARRISON, *Chairman.*

Chicago, March 9, 1934.

## Appendix E

## (6) BIBLIOGRAPHY ON SUBJECTS PERTAINING TO YARDS AND TERMINALS APPEARING IN CURRENT PERIODICALS

Compiled by E. E. R. Tratman

E. E. R. Tratman, Chairman, Sub-Committee; C. E. Armstrong, C. J. Astrue, H. M. Bassett, N. C. L. Brown, R. B. Elsworth, E. H. Fritch, J. V. Hanna, M. J. J. Harrison, W. J. Hedley, Noah Johnson, E. T. Johnston, A. E. Owen, W. C. Sadler, and H. L. Vandament.

## (A) PASSENGER STATIONS AND TERMINALS

- Atlantic City—Union Station project—Engineering News-Record, 1932, November 3, page 539.
- Boston—Boston Elevated Railway—Engineering News-Record, 1932, November 3, page 527.
- Chicago—Illinois Central—Suburban electric passenger terminal—Railway Age, 1932, October 29, page 605.
- Chicago—Union Station—Steam service plant—Railway Age, 1932, October 15, page 539.
- Chicago—Union Station—Mail terminal at new post-office over tracks—Railway Age, 1933, January 21, page 71.
- Cincinnati—Union Station—Engineering News-Record, 1933; February 2, page 101; April 6, page 448—Railway Age—1933, January 14, page 41; April 22, page 575.—Wood Preserving News, 1933, June, page 75.
- Dayton—Union Station and track elevation—Railway Age, 1932, October 1, page 466; December 17, page 899.
- East St. Louis—New union station and approaches—The Illinois Engineer, 1933, January.
- Hamilton—Canadian National Railways—Canadian Railway and Marine World, 1933, June, page 277.
- Hamilton—Toronto, Hamilton & Buffalo Ry.—Canadian Railway and Marine World, 1932, December, page 627; February, page 66.
- Hoboken—Delaware, Lackawanna & Western Railway—Painting train-shed with spray gun—Railway Engineering and Maintenance, 1932, November, page 660.
- Houston—Southern Pacific Railway—Engineering News-Record, 1933, May 18, page 666.
- Johannesburg—South African Government Railways—Engineering News-Record, 1933, January 12, page 68—Railway Gazette (London) 1932, December 16, page 739.
- Los Angeles—Union Station—Engineering News-Record, 1932, October 27, page 513.
- Mexico—Union Station; National Railways of Mexico—Engineering News-Record, 1933, April 6, page 447.
- Montreal—Canadian National Railways—Engineering News-Record, 1933, February 2, page 160—Canadian Railway and Marine World, 1933, June, page 255.
- Newark—Pennsylvania Railroad; new station for electrified line—Railway Age, 1933, February 25, page 272.
- New York—Subway stations—Civil Engineering, 1932, October, page 605; 1933, January, page 22.
- Philadelphia—Pennsylvania Railroad; new stations—Engineering News-Record, 1933, February 2, page 160—Railway Age, 1933, February 25, page 269.
- Portland—Union station project—Railway Age, 1932, October 29, page 622.
- St. John—Canadian Railway and Marine World, 1933, April, page 157.
- Baggage elevators—Proceedings, American Railway Engineering Association, 1933, Bulletin 354, page 682.
- City planning in relation to terminals—Civil Engineering, 1932, December, page 751.
- Drainage of terminals—Proceedings, American Railway Engineering Association, 1933, Bulletin 349, page 136.
- Grade separation and terminals—Detroit; planned by railways and municipal commission—Railway Age, 1932, October 8 and 22, p. 494 and 561—Louisville; Kentucky & Indiana Terminal Railroad—Railway Age, 1932, September 17, page 398.
- Joint facilities; records—Proceedings, American Railway Engineering Association, 1933, Bulletin 350, page 234.
- Motor coach service—Maine Central Railroad and Reading Railroad—Railway Age, 1932, September 24, pages 439 and 443.

- Snow protection and removal—Proceedings, American Railway Engineering Association, 1933, Bulletins 349 and 351, pages 159, 162 and 358.  
Valuation and terminals; New York, New Haven & Hartford Railroad—Railway Age, 1932, November 26, page 754.

### (B) FREIGHT STATIONS, TERMINALS AND YARDS

- Albany—Grain elevator of novel construction—Engineering News-Record, 1933, Construction Methods, 1933, February, page 12; March, page 26.  
Galesburg—Chicago, Burlington & Quincy, Railroad—Reconstruction of gravity yard—Railway Age, 1932, December 24, page 938.  
March—London & Northeastern Railway (England)—Gravity yard with magnetic car retarders—Railway Gazette (London), 1933, February 24 and March 3, pages 245, 282, 288.  
Marquette—Duluth, South Shore & Atlantic Railway. Ore Dock—Railway Age, 1933, March 4, page 326.  
Osterfeld—German State Railways; gravity yard—Bulletin of International Railway Congress, 1933, April, page 331.  
New York—New York Port Authority; proposed freight tunnel to Brooklyn—Railway Age, 1932, October 29, page 623.  
New York—New York Central Railroad; terminal on West 14th St.—Railway Age, 1932, September 24, page 449.  
New York—New York Central Railroad; west side improvements—Engineering News-Record, 1933, February 2, page 162.  
New York—Union inland or off-rail terminal; New York Port Authority—Engineering News-Record, 1932, December 29, page 768. Architectural Record, 1933, April, page 275. Railway Age, 1933, March 25, page 440. World Ports, 1932, page 919; 1933, January, page 14.  
Portland—Proposed union terminal—Railway Age, 1932, October 29, page 622.  
Vancouver—Canadian Pacific Railway. Tunnel approach to terminal—Canadian Railway and Marine World, 1932, September, page 451.  
Car Retarders—Magnetic system on London & Northeastern Railway (England)—Railway Gazette (London), 1933, February 24, page 245.  
Container System—Railway Age, 1932, September 17 and December 24, pages 389 and 955.  
Containers—Foreign developments—Bulletin of International Railway Congress, 1933, April, page 418.  
Door to Door Service—Railway Age, 1932, December 3 and 24, pages 830 and 953; 1933, April 15, page 543; April 22, pages 595 and 597; May 27, pages 753, 755 and 777. Canadian Railway and Marine World, 1933, January, page 3; April, page 155.  
Door to Door Services—Long Island Railroad; Railway Age, 1932, October 1, page 478—Pennsylvania Railroad; Railway Age, 1933, March 18 and April 22, pages 402 and 597.—St. Louis Southwestern Railway; Railway Age, 1933, March 25, page 452—Southern Pacific Railway; Railway Age, 1932, December 24, page 953.—Texas & New Orleans Railway (Southern Pacific Transport Company); Railway Age, 1933, January 28, page 115.  
Elevators—Freight station—Proceedings, American Railway Engineering Association, 1933, Bulletin 354, page 683.  
Engine Terminals—Heating methods, firing-up stations and turntables—Proceedings, American Railway Engineering Association, 1933, Bulletins 349 and 350, pages 77, 252, 254 and 256.  
Freight terminals—City planning relations—Civil Engineering, 1932, December, page 751.  
Freight Terminals—Elevators—Proceedings, American Railway Engineering Association, 1933, Bulletin 354, page 682.

Freight terminals—Reduction in delays—Railway Age, 1932, December 3 and 31, pages 829 and 969; 1933, April 22, page 591. Journal of Western Society of Engineers, 1933, April, page 72.  
Freight yards—Drainage methods—Proceedings, American Railway Engineering Association, 1933, Bulletin 349, page 135.  
Freight yards—Hump and retarder system; design—Proceedings, American Railway Engineering Association, 1933, Bulletin 350, pages 168 and 177. Engineering News-Record, 1933, March 23, page 383.

- Freight yards—Improvements—Railway Age, 1932, December 3, page 839.
- Freight yards—Snow protection and removal—Proceedings, American Railway Engineering Association, 1933, Bulletin 349 and 351, pages 159, 162 and 358.
- Grain elevator—Novel design at Albany—Engineering News-Record, 1933, ..... Construction Methods, 1933, February, page 12; March, page 26.
- Mail terminal—Chicago post office—Railway Age, 1933, January 21, page 71.
- Ore dock—Duluth, South Shore & Atlantic Railroad; at Marquette, Mich.—Railway Age, 1933, March 4, page 326.
- Platforms—Produce terminals—Proceedings, American Railway Engineering Association, 1933, Bulletin 350, page 175.
- Poultry terminal—At New York—Architectural Record, 1933, May, page 50.
- Produce terminal—Buffalo, N. Y.—Railway Age, 1932, October 22 and 29, pages 565 and 613.
- Produce terminals—Buildings; cold storage temperatures—Proceedings, American Railway Engineering Association, 1933, Bulletin 354, page 694.
- Produce terminals—Design—Proceedings, American Railway Engineering Association, 1933, Bulletins 350 and 354, pages 173 and 694. Engineering News-Record, 1933, March 23, page 383. Railway Age, 1932, October 29, page 565.
- Produce terminals—Interstate Commerce Commission's report—Railway Age, 1932, October 29, page 613.
- Switching charges for terminals—Railway Age, 1932, September 3, page 342.
- Switching locomotives—Oil-electric—Jay St. Line, Brooklyn; Railway Age, 1932, December 31, page 975—New York Central Railroad; Canadian Railway and Marine World, 1933, March, page 93.
- Track Scales—Test cars—Proceedings, American Railway Engineering Association, 1933, Bulletin 350, pages 169 and 197.
- Truck and bus service—Maine Central Railroad and Pennsylvania Railroad—Railway Age, 1932, September 24, pages 439 and 443.
- Trucking—Reading Railroad and Spokane, Portland & Seattle Railroad—Railway Age, 1932, October 22, pages 579 and 583.
- Trucking—Survey of service; regulation—Railway Age, 1932, September 10, October 8 and November 5, pages 363, 372, 493 and 639.
- Turntables—Proceedings, American Railway Engineering Association, 1933, Bulletins 349 and 350, pages 77 and 254.
- Warehouse—Remodeled; Economy Grocery Stores Corporation—Architectural Record, 1933, February, page 121.
- Warehouses—Storage charges—Railway Age, 1933, March 18, page 402.

### (C) RAIL AND WATER TERMINALS

- Colona—Pittsburgh & Lake Erie Railroad—Coal transfer plant on Ohio River—Railway Age, 1932, December 17, page 909.
- Los Angeles—Pier design—Engineering News-Record, 1933, March 9, page 305. World Ports, 1933, February, page 18.
- New York—Piers 1100 ft. long—Engineering News-Record, 1933, March 9, page 331. World Ports, 1932, page 875.
- St. John—Canadian Railway and Marine World, 1933, May, page 241. World Ports, 1933, February, page 10.
- Seattle—Passenger and freight facilities—World Ports, 1933, April, page 18.
- Car Ferries—Florida East Coast Railway, to New Orleans and Havana—Railway Age, 1932, October 29, page 623.
- Car ferry—Seatrains line and steamer "Seatrains"—Railway Age, 1932, September 17, October 15 and 29, pages 412, 551 and 623; 1933, January 28, page 123. Marine Engineering, 1932, October. Marine Review, 1933, April, page 18.
- Lighterage charges—New York—Railway Age, 1933, February 4, page 195.
- Marine terminals—Building codes and fire protection—World Ports, 1932, December, page 77.
- Marine terminals—Design and operation—World Ports, 1933, January, page 10.
- Marine terminals—Public ownership of rail-water terminals—World Ports, 1932, October—November, page 38; 1933, January, page 21.
- Marine terminals—Unification of railway facilities—World Ports, 1932, page 909.
- Pier design—Los Angeles and New York—Engineering News-Record 1933, March 9, pages 305 and 331. World Ports, 1932, page 875; 1933, February, page 18.
- Waterway policy of United States—Railway Age, 1932, September 24, page 433.

## (D) AIRPORTS

Air express development—Speed, 1933, April, page 9.

Air-rail express service—Railway Age, 1933, April 1, page 477.

Airports—Coordination with railway facilities—Proceedings, American Railway Engineering Association, 1933, Bulletin 350, page 189.

Airports—Tulsa, Oklahoma—Speed, 1933, January, page 8.

## Appendix F

(7) THE EXPEDITING OF FREIGHT CAR MOVEMENTS  
THROUGH YARDS

W. F. Cummings, Chairman, Sub-Committee; J. R. W. Ambrose, J. E. Armstrong, H. M. Bassett, N. C. L. Brown, H. F. Burch, R. J. Hammond, G. F. Hand, J. V. Hanna, M. J. J. Harrison, E. M. Hastings, W. J. Hedley, W. H. Hobbs, E. T. Johnston, L. L. Lyford, C. H. Mottier, T. R. Ratcliff, W. B. Rudd, E. E. R. Tratman, H. L. Vandament and H. M. Waite.

The Committee has restricted its report this year to a generalization of the subject with the intention, if the subject is continued, of carrying its study to more specific details.

For many years the freight yard has been recognized as a major factor in delays to car movements. Much time and consideration has been given to the subject. Much stress has been given it in books, technical papers, proceedings, etc. In 1918, John F. Wallace, speaking before the Association of Commerce at Chicago, said (Vol. 20—pp. 174-175 A.R.E.A. Proceedings):

"The Terminal problem is really the big problem of our railroad transportation system, and its solution will automatically solve most of our transportation complexities.

"While the total mileage of terminal tracks may not be too much—and in certain localities may even be insufficient—the remedy lies not entirely in additional tracks and facilities, but in a correlation and readjusting of existing facilities and the operation within the terminal zone along lines that will secure the maximum of efficiency.

"Viewed from the standpoint of delays, the railway terminal becomes even a larger factor in the transportation problem. The average freight car travels about twenty-five miles a day. The average speed of a freight train between terminals is ten or fifteen miles an hour. It is, therefore, evident that the average freight car spends twelve hours in the terminal for every hour it spends between terminals.

"Since the remedy—whatever it may be—will eventually be applied by Congress, it is highly important that the general public comprehend the fundamentals of the present transportation situation and the general nature of the changes in operation and control necessary to bring about a more efficiently operated transportation system.

"These changes will necessarily be of two kinds:—First, physical changes in terminal facilities; and, Second, changes in method of operation.

"The interchange freight should receive first consideration. It frequently happens that a car of commodities consigned from a point in the West to a point in the East is handled successively by several railroads and at every place where it passes from one railroad to another it goes through a terminal, often passing through the hands of an intermediate company, occupying space in several railroad yards, congesting interchange tracks and encountering days of delay.

"The remedy for this condition is more direct routing—and a routing that will pass the car around rather than through the larger railroad terminals. ...."

In a paper written in 1919 by E. H. Lee, Vice-President of the Chicago and Western Indiana Railroad Company, and appearing on pp. 180-188—Vol. 20 of the Proceedings of this Association, there appear among other things these comments—

"It may be well to briefly review the conditions as they now exist, although such a review will contain a statement of facts which are well known to most railroad men, and are coming to be better known by the general public and which may, therefore, seem more or less trite.

"Until about ten years ago the railroads of the country expended great sums of money for double track, the reduction of grades, the extension of sidetracks, the construction of new branch lines, and other facilities for accumulating traffic and handling it more expeditiously to the terminals, without any corresponding expenditure to improve facilities in the terminals themselves. Recently more of an effort has been made to improve and enlarge terminals; but on many of the railroads the important terminal facilities in the larger cities are in great measure what they were ten years ago. Although from the nature of the case, since early in the history of the railroad industry, terminals have been the principal points of congestion, this tendency has become greatly aggravated during recent years. It is not too much to say that at this time the capacity of the larger terminals of the country are the measure of the transportation output which can be delivered by the railroads.

\* \* \* \* \*

"Of the requirements mentioned as fundamentally necessary for the efficient manufacture of transportation only one remains, viz., good methods and practices. It is just here, in the view of the writer, that important changes and improvements may be made which will quite radically improve the efficiency of the railroad as a whole, because they will reduce congestion in the terminals, this being, as already stated, the chief enemy to transportation efficiency as a whole.

"Congestion is defined as a condition of undue pressure, a state of unnatural crowding; and congestion on the railroads, like congestion in the body, is a disease which interferes with the normal functions, and is to be reduced by the use of various devices and means adapted to remove the undue pressure in the parts affected.

"Two of the principal causes of congestion in terminals, which in turn act in a vicious circle with congestion itself, each to cause the growth of the other, are dead time and the rehandling of cars. It is safe to say that any method or practice which secures the maximum reduction in dead time, and in the rehandling of cars, will also secure maximum reduction in the congestion of terminals, and, therefore, maximum increase in the efficiency of the railroads of the country as a whole.

"For the purpose of this discussion, dead time is limited to and may be defined as time spent by the train crew after an engine has been manned, in getting out of the roundhouse, pulling up to and coupling onto the train, testing the air, etc., at the outgoing end of the trip; time lost in setting out and picking up; and time spent in putting away the train with the various similar attendant operations at the incoming end. This so-called dead time thus defined is to be distinguishable from time spent in actually passing over the road. Its serious effect in terminal operations is not generally appreciated being of much less relative importance in open country operation than in terminal operation.

"This is true because dead time remains more or less constant, while running time tends to vary directly with the length of the run. As an illustration—assume an open country division 100 miles long, average freight running time over the division 8 hours; as compared with a transfer run in a terminal 12 miles long, average running time 1 hour. If the dead time is in each case two hours, the dead time loss on the country division is only 20 percent, whereas on the transfer run it is 66⅔ percent.

"This comparison may seem exaggerated, but an investigation made by the writer some years ago, which is believed to have been reasonably accurate, disclosed that in an actual case under ordinary conditions and where no undue congestion existed dead time as above defined consumed 65 percent of the total service time of all transfer trains.

"Rehandling cars is brought about by a number of different causes. Lack of proper method, as well as lack of careful and intelligent planning on the part of trainmasters, yardmasters and conductors responsible for transfer movements, is partly responsible, but these causes operate during times of normal movement as well as during times of congestion. The great cause for rehandling is undoubtedly congestion, which is in turn further aggravated by the rehandling itself.

\* \* \* \* \*

"At most minor terminals and junction points, direct deliveries are made between the railroads, and at some points the chief improvement possible is doubtless to be secured by a coordination of facilities when practicable, and an improvement in methods, as, for instance, by the reciprocal delivery of cars, thereby eliminating light running. In the case of industries served by more than one line, it has been the general practice in the past for each road to handle its own business into and out of the same, although in one case familiar to the writer all such industrial deliveries have been handled by a terminal

railroad for the tenant companies using its line for a period of over 30 years, and with results entirely satisfactory in the way of a reduction of both engine time and cost.

\* \* \* \* \*

"The three things among those suggested in this discussion which it is believed would have especial effort in controlling congestion are the construction of storage yards, outside the terminals; the advance classification of transfer cars, to the greatest practicable extent; and an extension of the authority of the men in charge of terminal operations, whatever their rank or title, in order that they may better control the flow of traffic to and through the terminal."

If these observations, comments and conclusions as to the seriousness of congestion and delays in terminals were worth while considering then, they surely are today, because, whereas delays and congestion at that time merely meant handicap to business and criticism of the railroads, today it definitely means loss of business because of the competition of the highway motor vehicles. Many equally good observations could be quoted from other eminent authorities to show the importance of terminal delays.

In view of the present conditions of competing services, the present duplication of services and facilities, general demands for quicker movements of freight to permit reduction of stock supplies, etc., the continuing loss of business to the motor transport, the desirability of maintaining a favorable attitude of the public toward the railroad by meeting reasonable demands and requirements, the insistent demands for a reduction in freight rates, etc., it is apparent to all of us that now more than ever must we give service.

We are all aware of the recent trend in transportation towards increased speed and prompt delivery of all classes of freight and the fact that results are being obtained. The reduction in time has been accomplished by greatly increased road speed and by improved operating methods in terminals. This Committee interprets its assignment to outline the proper facilities for such operation. The subject might be generally subdivided as follows:

- (a)—Movement from point of origin to first departure. This includes industrial switching, transfer movements and primary classification.
- (b)—Movement through intermediate yards.
  - (b-1)—Major intermediate yards where trains are broken up such as at important interchange points and reclassification points.
  - (b-2)—Secondary intermediate yards where through freights are main-tracked. Tonnage may be added or subtracted at these points. It may be necessary to change power and usually is necessary to change cabooses.
- (c)—Movement from last terminal to destination, which is, of course, the reverse of (a).

The problem is affected among other things by—

- Operating program and routine.
- Yard and terminal design.
- Construction and operating economies.
- Loading and unloading methods of shippers and consignees.
- Public body regulations.
- Highway truck movements between terminals and points of origin and destination.
- Co-operation at transfer points as between railroads.

The first consideration should be to study improved methods of operation, many of which are in effect on railways today. These include among others—

Improved methods of classification over the entire system, assigning particular duties to each yard and obtaining a clear idea as to what is to be done at each terminal.

The quick assembling and get away of freight trains when freight houses are closed.

The quick assembling of cars from industries and other railroads.

The advance classification of cars on one railroad for another.

The running of locomotives of one railroad through on others.

The unification and coordination in use of terminals.

The use of smaller and lighter equipment on short haul work.

The segregation of short haul work.

The use of off-rail terminals.

Use of container cars.

Use of demountable body cars or cars adjusted to rail and highway service.

This having been done, there should then be the planning of proper facilities to carry out the operating program. Some of the features that may help to speed up the movement through yards are—

Main tracking of trains.

Hump Yards.

Installation of Car Retarders.

Main track coaling stations so arranged that coal, water and sand can be taken at the same stop, particularly at intermediate yards where power is run through and trains main-tracked as much as possible.

High speed turnouts at yard entrances and other locations.

Power operated turnouts at yard entrances and other locations.

Tracks of sufficient length to accommodate trains without doubling.

Floodlights for night switching.

Hot oiling facilities.

Communication facilities, (teletype, pneumatic tubes, loud speaker, etc.)

Air lines in receiving and departure yards.

Good alinement on running tracks.

Good gradients on running tracks.

Signals on long running tracks used in both directions.

Proper spacing of tracks in receiving and departure yards to facilitate inspection and light running repairs.

Proper design at hump end of receiving yards and entrances and exits of flat yards to release road power with minimum interference.

Compact arrangement of turnouts in flat yards to minimize time necessary to throw switches and for switching.

Proper length of ladders in flat yards to avoid unnecessary engine mileage.

Proper length of classification tracks in flat yards to avoid unnecessary engine mileage.

Proper gradients for ladders and body tracks in flat yards.

Good visibility particularly on ladders and drill tracks in flat yards.

Convenient and proper location and size of—

Light repair tracks.

Icing stations.

Poultry feeding platforms, etc.

Classification yards with respect to points of interchange with other railroads and industries and freight houses, as well as number of tracks with relation to number of classifications.

Secondary classification yards.

Receiving yards in relation to classification yards.

Hold tracks.

Departure tracks.

Caboose tracks.

Engine facilities.

The question of terminal delays has been given attention by this and other committees of this Association heretofore. In Vol. 19, pp. 316 to 323, is a report on War Emergency Yard Improvements, and in Vol. 20, pp. 159 to 172 inclusive is an excellent

report on the unit operation of large terminals, including a Catechism on Unit Operations of Railroad Terminals, which this Committee recommends as being timely.

From time to time Committee XIV—Yards and Terminals, Committee XVIII—Electricity and Committee XXI—Economics of Railway Operation have reported as to good practice with respect to some of the items which this Committee has stated above may help to expedite the movement of freight cars through yards. For ready reference a tabulation of such is given herewith.

\* Died October 17, 1933.

### *To the American Railway Engineering Association:*

Your Committee presents herewith report on the following subjects:

(2) Standardization of parts and accessories for railway maintenance motor cars (Appendix A). It is recommended that this report be adopted for publication in the Manual as recommended practice.

(3) Adaptability of air and electric driven tools in maintenance of way work. A report on track grinders (Appendix B) is submitted as information.

(4) Types of snow-melting devices as an aid in facilitating train operation and reducing maintenance cost (Appendix C). This report is submitted as information.

(5) Use and adaptability of track type tractors in maintenance of way work (Appendix D). This report is submitted as information.

(11) Use of weed destroying equipment, including horse-drawn and power mowers operating both on and off the track (Appendix E). This report is submitted as information.

(13) Track welding equipment (a) oxy-acetylene; (b) electric arc (Appendix F). This report is submitted as information.

(15) Use and maintenance of paint spraying equipment with outline of typical organizations for various classes of work (Appendix G). Hazards of spray painting (Appendix H). This report is submitted as information.

(16) Use and maintenance of ballast cleaning machines and conditions under which each particular type may be used (Appendix I). This report is submitted as information.

Progress is reported on the following subjects:

(1) Revision of Manual.

(6) Methods of keeping data on work equipment and labor-saving devices.

(7) The selection and training of maintainers and operators of work equipment.

- (8) Use of ballast discers.
- (9) Organization for the use of tie-tamping machines, air and electric.
- (10) Rail laying machines and auxiliary equipment.
- (12) Tie adzing, scoring and boring machines.
- (14) Prepare manual of instructions for care and operation of maintenance of way work equipment.
- (17) Use of oil spraying machines for oiling rails and fastenings, steel structures and roadbed.

---

**Almon I. Gauthier**

It is with profound sorrow that the Committee announces the sudden passing of Almon I. Gauthier, Assistant Division Engineer, Boston & Maine Railroad, Concord, N. H., on October 17, 1933, who at the time of his death was Chairman of Sub-Committee 12—Tie Adzing, Scoring and Boring Machines.

Mr. Gauthier's contribution to the work of our Committee, together with his splendid personality, will make his loss keenly felt by every member of the Committee.

Respectfully submitted,

THE COMMITTEE ON MAINTENANCE OF WAY WORK EQUIPMENT,

C. R. KNOWLES, *Chairman*.

**Appendix A**

**(2) STANDARDIZATION OF PARTS AND ACCESSORIES FOR  
RAILWAY MAINTENANCE MOTOR CARS**

G. R. Westcott, Chairman, Sub-Committee; Walter Constance, G. J. Ermentrout, Paul Hamilton, R. C. Haynes, Jack Largent, E. H. Mills, C. H. Ordas, J. G. Sheldrick, N. M. Trapnell, J. M. Trissal.

Continuing the studies of previous years your Committee has had under consideration a number of items on which recommendations have not previously been made, namely loose wheels, lubrication of axle bearings and types of shut-off cocks.

Details of these features, particularly the bushings and bearings for loose wheels, were not presented because of the fact that tests were being conducted by motor car manufacturers with the use of metal bushing.

The question of type and kind of grease cup for lubrication of axle bearings has also been given a great deal of study with a view of making definite recommendation. The development of a gasoline shut-off cock that will meet all requirements of reliability and safety is another subject that has been given careful consideration by the Committee. It is expected that we will be in a position to present report with recommendation on the above-mentioned features next year.

Progress is also reported on other details of ignition systems as well as some accessories, such as axle bearing thrust collars, belt pulleys, battery boxes, coils, etc.

## Appendix B

(3) ADAPTABILITY OF AIR AND ELECTRIC DRIVEN TOOLS IN  
MAINTENANCE OF WAY WORK

M. D. Bowen, Chairman, Sub-Committee; G. E. Boyd, W. O. Cudworth, J. J. Davis, Robert Faries, C. L. Fero, H. I. Hoag, Harry Homans, J. S. Huntoon, C. H. Morse, T. M. Pittman, L. J. Turner.

## TRACK GRINDERS

Track grinders have been designed and built to provide a more satisfactory and economical means of finishing welds on rail, frogs, and crossings, as well as grinding off overflowed metal at switch points and stock rails, and in some cases on the low side of curves. There are various types of track grinding machines designed to meet the varying conditions as found on different railroads.

Owing to the lack of suitable grinding machines in the early days of gas welding the best work was obtained by the use of the flatter, and it is only recently that suitable grinders have become available. A much better surface can be obtained by grinding after welding. The different types of grinders now on the market may be divided into two general classes (a) those equipped with revolving wheels, and (b) those known as reciprocating grinders, where a group of carborundum blocks is carried in a frame or crosshead, sliding back and forth on guides. The movement is generated by a connecting rod from a crank disc on a cross shaft driven by the engine and the cutting speed is necessarily low, being not over 300 surface feet per minute. Consequently the grinding is slow, but a perfect job is done; the blocks soon take the contour of the rail heads, the finished work is true and the two rail heads are brought to an absolutely level surface.

There are two kinds of reciprocating grinders—a double sided heavy four-wheel machine equipped with a Ford power plant, and a light portable two-wheeled machine which may be easily removed from the track to permit the passage of trains. Naturally the former does the fastest work, grinding the joints first on one rail and then the next joint on the other rail of the track. The portable machine operates on one rail only.

The grinders equipped with revolving wheels are much faster, the cutting speed of wheels with bakelite or other synthetic bonds running up to 10,000 surface feet per minute. The revolving wheel machines may be divided into two classes—those using cup wheels and those using disc wheels. The former may be the free-hand type, driven by a flexible shaft, or they may be the precision type where the wheel is carried by a crosshead sliding on guides, the machine being clamped to the track.

Revolving disc wheel track grinders may be further divided into two classes. In the first class are constant speed machines which are designed to maintain a uniform r.p.m. The second class will be considered the variable speed track grinders which are provided with a range of speeds in order that a predetermined surface speed may be maintained as the wheel is worn to a smaller diameter.

As an example of the importance of the speed adjustment on track grinders, on the basis of 10,000 peripheral feet per minute at 12 inches wheel diameter, if the revolutions per minute remain constant, the wheel will lose approximately  $33\frac{1}{3}$  per cent of its efficiency when it is reduced to 8 inches.

The disc wheel grinders may be of the free-hand type, driven by a flexible shaft, the wheel and guard being mounted in a suitable holder. This device is not the most satisfactory, as it is difficult to prevent the wheel gouging in, resulting in a poor fin-

ished surface. A more satisfactory arrangement is to mount the wheel in a frame which can be raised and lowered by a hand wheel feed and moved from side to side of the rail head while the whole machine rolls back and forth along the rails over the joint being ground. This is not a precision grinder, although good work may be done rapidly. One disadvantage is the size and weight of the machine and the impossibility providing clearance for trains when placed in the intertrack space of a multiple track railroad. Another is that the machine rolls back and forth on the rail heads which are not true plane surfaces. Any irregularities in the surfaces of the rail heads will be reproduced in the ground joint. The wheels rolling on the rails may also be out of round, and care must be taken that the powdered metal and emery dust does not pile up on the rail.

Another disc wheel machine is of the precision type, in which the wheel is carried by a crosshead sliding on guides, the machine being clamped to the track.

In addition to the surface grinders, it is important to use a cross grinder for opening the slot between the rail ends at the joint. These machines are either single sided or double sided, the latter being moved along the track, slotting first one joint in one rail and then the next joint in the other rail. Some of these grinders are equipped with one thin wheel usually  $\frac{1}{8}$ -in. thick and others with two wheels, one  $\frac{1}{8}$ -in. thick for the tight joints and another thicker wheel for the open joints.

### Present Extent of Track Grinding Machines in Use

Questionnaires were sent to 30 railroads regarding the use of track grinders. Seven railroads report having track grinding machines of various kinds, types, and sizes in use; 5 railroads reported no grinders in service; 1 railroad reports observation of track grinding machines in use by contractors. Due to the fact that most of the track grinding machines on steam railways are comparatively new, detailed information as to their general operating efficiency is not available.

On account of recent demands for track grinding machines, numerous companies have developed grinders to be used in connection with the welding repairs of the track structure. As a matter of information grinders are confined to three general groups representing the kind of power used to drive the machines, namely, gasoline, electric and air.

The term "track grinder" will apply to all types of grinders used in the maintenance of track and will be classified under the three following sub-headings:

1. **SURFACE GRINDER.**—A surface grinder is designed primarily for finishing rail ends after welding. May be used for finishing frogs after welding and for grinding off side flow and irregularities on top or side of rail, frogs or switches.
2. **CROSS GRINDER.**—A cross grinder is designed primarily for removing end flow of rail to prevent chipping.
3. **SIDE FLOW GRINDER.**—A side flow grinder is designed primarily for removing the overflow on stock rails in frogs and switches and also for smoothing up switch points.

### Relative Merits of Various Types of Track Grinders

Relative merits will be listed as to their respective importance in carrying out the work efficiently and economically:

- (1) Attached chart compiled on a speed basis of 10,000 surface feet per minute shows the r.p.m. at which grinding wheels having a synthetic rosin bond should run. It will be noted that as the size of the wheel decreases the r.p.m. must increase in

C. M. ST. P. & P. R. R. Co.

SURFACE SPEED FOR GIVEN WHEEL SIZE AND R.P.M.

NOTES.—The diagonal line is the 10,000 ft. per minute line, or the line of perfect performance. All operation above the line would be in excess of 10,000 ft. per minute at any of the variable speeds, while those values below the line are for a fixed or constant speed and show the exact surface speed for that given r.p.m. The numbers also denote efficiency in per cent by inserting a decimal point before the last two digits. This efficiency is for any given r.p.m. directly to its left at the margin.

order to maintain a predetermined peripheral speed. It will be necessary to check and correct the grinding wheel speeds frequently in order to maintain a constant surface speed. Failure to maintain constant surface speed may result in losses of grinding wheel efficiency up to 75 per cent.

(2) Gasoline engines are a desirable and economical source of power in operating track grinders. These engines are equipped with mechanical governors and adjustments are provided to maintain the variable speeds required to completely wear out the grinding wheels. This wide range of speeds is not provided in any other form of power.

(3) It has been found, from observation of many different types of drives that the V-belt, wherever it can be used, provides a very efficient and trouble-proof method of driving track grinding wheels. There are some instances where metal flexible shafts, due to the peculiar nature of the work, are very desirable. They are usually used, however, in conjunction with V-belt drive assemblies.

(4) Lubrication of grinding machines cannot be overstressed. Low sodium soap types of greases are well adapted when various kinds of ball and roller bearings are used at very high speeds, such as are found in the better type of grinding machines. Ball bearings must run from approximately 2500 r.p.m. to 12,000 r.p.m. which requires very thorough lubrication. The chemical analysis of the grease referred to is approximately 95 per cent steam refined cylinder stock and 2 per cent to 5 per cent sodium soap, and is used in preference to lime soap greases.

(5) Air cleaners on gasoline motors and crank case oil breathers must be protected when engines are used on grinding machines, as the engines are required to operate in a virtual bath of emery dust. There are many types of air cleaners and breather caps on the market for this purpose, but few are efficient enough to be of any value under these conditions. The oil bath principle of carburetor air cleaners has proven more efficient than any other type so far developed. This type of cleaner requires daily care if the best results are to be obtained.

(6) Of the many methods being used of providing the vertical feed on track grinding machines, few are positive and fast enough to insure good workmanship in surface grinding when the grinding is being done on a production basis. It is essential that the feed be positive in its downward movement of the wheel, and at the same time be so designed that it will release instantly when the feed wheel is turned in the opposite direction. Machines have been developed where this feature was not considered, and there was slack in the feed mechanism that had to be removed before the adjustment would start to raise the wheel, which resulted in grinding holes beyond the end of the weld. This is not desirable, and creates a condition in ground rail ends that can only be detected for many months after completion of work.

(7) It is often considered necessary to apply excessive pressure to grinding wheels in order to maintain a rapid rate of cutting. It is more important to use light wheel pressures but maintain high peripheral speeds than it is to try to attempt to crowd a grinding wheel by creating excessive pressure.

Numerous changes and improvements on track grinders are now under way and further reports will be made to bring out the latest developments.

#### (4) TYPES OF SNOW-MELTING DEVICES AS AN AID IN FACILITATING TRAIN OPERATION AND REDUCING MAINTENANCE COST

F. S. Hewes, Chairman, Sub-Committee; J. F. Donovan, C. R. Edwards, C. L. Fero, A. I. Gauthier, R. C. Haynes, L. B. Holt, E. Pharand, J. M. Trissal.

##### Introduction

Due to the rather exhaustive treatment of the subject last year, the Committee has found very little data this year. The following is submitted on changes and additions to its previous report (pages 358 to 383 inclusive, Vol. 34 of the Proceedings).

##### General Discussion

While the fire hazard incident to the storage of oils was mentioned in the previous report, it should be emphasized that rules and regulations pertaining to the storage and handling of highly inflammable oils, such as casing head gasoline, hydro carbon and snow-melting oils, should be rigidly adhered to.

## Types

**CHEMICALS.**—2a. Calcium carbide is sometimes sprinkled on the snow around switches, frogs and guard rails, and the acetylene gas which is generated is ignited to melt the snow.

**HEATERS.**—9e. Hot-TraC: There are two designs of this oil burning pot. Both are made of cast iron, and each has a rather long and narrow wick which is parallel to the rail. One design (Fig. 25) is placed under the rail, but instead of resting on the ballast as is usually the case, it is suspended by a wire bracket or sling which also serves as a stop to hold the box in such a position that the wick falls just a little inside of the center of the rail base.

The other design (Fig. 26) is placed on top of the rail base where it is held in place by a wire bracket, the wick being alongside of the web of the rail.

11. Concrete snow-melting pits are now made deeper than shown in Fig. 8 of last year's report, and the drain is raised to permit the accumulation of a layer of hot water at the bottom of the pit, so snow is shoveled into the boiling water.

Barrels heated with a steam hose are also used to melt snow shoveled into them.

17a. Elec-TraC: The housing for this melter is now made of cast iron instead of pressed copper bearing steel as heretofore, otherwise it is essentially as described last year.

17g. Nu-TraC: An electric melter with a heating coil similar to that used in the Elec-TraC. The coil is housed in a cast iron box which is held in contact with the bottom of rail base by a wire clip. (Fig. 27)

devices are used.

## Conclusion

Under proper conditions, snow-melting devices are an aid in facilitating train operation and reducing maintenance expense. There are many types available. The best type and design for the purpose is worthy of study.

## Appendix D

### (5) USE AND ADAPTABILITY OF TRACK TYPE TRACTORS IN MAINTENANCE OF WAY WORK

T. M. Pittman, Chairman, Sub-Committee; G. E. Boyd, W. O. Cudworth, G. J. Ermentrout, J. S. Huntoon, R. A. Morrison, H. W. Stetson, J. B. Trenholm, G. R. Westcott.

Supplementing our report at the last convention, which dealt with the general description and adaptability of track type tractors, your Committee desires this year to present a report on some specific operations of such tractors used in conjunction with certain specially designed attachments which adapt the machine to various uses, and to offer a method by which the qualities and merits of tractors offered by the various manufacturers may be compared more intelligently and systematically, thereby arriving at a selection of such a machine on the basis of its total score on a number of points rather than on a few emphasized by the manufacturer.

For convenience, the report will be divided into two parts; Part I dealing with the attachments and Part II presenting the scoring sheet.

#### PART I

#### FRONT END LOADER

One of the most striking examples of the versatility of track type tractors and their adaptability for maintenance of way work through the use of various attachments is afforded by relatively recent experiences with an attachment generally known as the front end loader.

The operation of this attachment is shown by the accompanying photographs. The attachment is entirely independent of the tractor, but is designed to fit the sizes of tractors best suited for railroad work and requires about 16 man hours for attaching to the standard tractor. This loader consists of a bucket, or scoop, attached to the front end of the tractor, is designed mechanically so that the scoop may be loaded by the power of the tractor as it travels forward. By means of different heights of mast or boom this scoop can be raised high enough to dump over the side of a gondola car, approximately  $8\frac{1}{2}$  feet; by using additional sections in the hoisting boom the lift of the scoop can be increased. The boom may be folded for convenience in loading into cars or for entry into buildings with low doors without having to remove the extra sections of the boom. The scoops are available in a number of sizes to fit the material being handled, ranging from  $\frac{1}{3}$  cu. yd. to 1 cu. yd., the smaller sizes being used for heavy material, such as wet dirt and gravel and the larger sizes for lighter material, such as cinders or snow or for cleaning litter from stock pens. The size best adapted for general use holds  $\frac{3}{4}$  cu. yd.

Various means of operating the scoop are employed, but in practically all cases the scoop can be handled by the operator of the machine. In some designs the scoops are controlled by a means of cables actuated by a mechanical hoist attached to the rear of the tractor. Others are operated by an hydraulic cylinder, the oil pressure being obtained from an hydraulic pump mounted on the rear of the tractor and driven by the tractor engine.

Another design of front end loader has the bucket attached to two side rods which run along the sides of the tractor and are hinged to a post fastened to the rear end of the tractor. The bucket is raised and lowered in a vertical arc with a radius the length

of the side rods. In this type the mounting on the rear will serve as a counterbalance. Some designs permit of every operation being controlled with one lever, which raises, lowers, holds and discharges the load, as well as flaps the bucket to dislodge sticky material.

A tractor equipped with this attachment will perform practically any operation as well as the ordinary power shovel of comparable bucket capacity and boom length and is even more versatile when used as a tractor to haul wagons, or equipped with a bulldozer for spreading material after it has been deposited.

For light material the scoop can be used as a bulldozer and the material piled in windrows for more convenient loading, or the scoop can be removed and a hood and sheaves attached so the machine can be utilized as a derrick capable of handling loads of a ton or more.

For more extensive bulldozing operations the scoop can be removed and a bulldozer blade attached. This change can be made in about ten minutes without disturbing the loader attachment. The bulldozer can be set square across the front of the tractor or at an angle for side casting. It can be adjusted to cut 11 inches below the treads of the tractor or can be raised to operate at any height desired consistent with the height of boom being used. This auxiliary device is especially useful in spreading material removed from ditches and in snow removal.

The outfit is adapted to many classes of work and the method of operation is simple and obvious. The scoop can be set for digging at any elevation from 6 inches below the tractor treads to 6 feet above and can be worked in any intermediate position. In ditching, the scoop is set to the desired height and the tractor is then moved forward, usually in low gear, to secure the most power, and the scoop driven into the material. When the scoop is full it is raised to the carrying position on the boom and the tractor is operated in a high speed to the dumping point. The ability of the tractor to move forward or backward and to turn in a very small space is particularly valuable in this operation. The material can be dumped into wagons or cars, or it may be deposited over the edge of an embankment or on a fill where it is desired to raise the grade. The  $\frac{3}{4}$  yard scoop is as wide as the tractor and a distinct advantage in ditching with this outfit is that the tractor travels behind the scoop on the smooth ground of the finished ditch, which facilitates the holding of a uniform grade through the ditch by maintaining the scoop at the proper elevation, whereas when a scoop is operated behind the tractor it is necessary for the tractor to operate over uneven ground, which makes it difficult to keep the bottom of the finished ditch at a uniform grade.

The same general method is followed for loading material from piles or for digging into the face of an embankment and it will be noted that the hoisting boom is so designed that while the scoop is in the loading position the edge is pointed downward, whereas when lifted to the carrying position the scoop assumes a pronounced back tilt, which prevents spillage of the material during transportation. Some scoops may be provided with a nose guard to assist in handling loose material, such as washed gravel, etc., which have a very flat angle of repose.

The attachment has been designed to maintain, as far as possible, the poise of the machine and counterbalances and/or safety valves have been provided in some cases to limit the power which may be applied in raising the scoop, thereby preventing the overbalancing of the machine in case a tree root or other obstacle is encountered. These safety devices can be adjusted to suit local conditions.

Some of the accompanying photographs show a front end loader being used to excellent advantage handling snow in a large railroad terminal in Chicago in February, 1933.

The snow fell to a depth of 13 inches and was followed by a drop in temperature to 20 degrees below zero. The streets and driveways leading to the freight warehouses and mail and baggage rooms were blocked by heavy drifts and many tracks were likewise blocked. A track type tractor equipped with side casting bulldozer was driven down the streets and driveways and the snow piled into windrows. The bulldozer was then replaced with a scoop and material loaded into dump wagons and gondola cars. After loading the wagons, the tractor towed them to a dumping ground. Only one man was used per machine and no difficulties were experienced on account of the extremely low temperature nor in driving the tractors over curbs and tracks or heavily drifted snow.

No reliable data on the cost of this operation are available, but the officers in charge report that four tractors placed at different yards and warehouses opened up the driveways to permit practically uninterrupted service. In former years this task had required the services of several hundred men, with less satisfactory results. These tractors are used on various maintenance of way work during the summer, but in the late fall they are moved to Chicago, where they are inspected, necessary repairs made and held in readiness for a snowstorm.

The use of track type tractors equipped with front end loaders and bulldozers offers possibilities for efficient and economical snow handling, economy being especially apparent when the use of the equipment on other work during the summer is considered. Various methods of operation will be suggested by local conditions but in general the snow is plowed from the driveways and tracks into piles of windrows. In other cases it can be plowed into catchbasins or melting pits. For quick opening up of freight houses, lanes can be plowed adjacent to the house or the snow can be piled in the spaces between the doors, leaving lanes the width of the doors leading from the doors to the main driveway.

Front End Loader—Using Bucket as a Bull Dozer to Pile up Snow for Loading.

The cost of operating a machine of this type on one ditching job was as follows:

|                           |     |
|---------------------------|-----|
| Gasoline, 2½ gal. @ ..... | 30¢ |
| Oil and grease .....      | 7¢  |
| Operator .....            | 50¢ |

Total operating cost per hour ..... 87¢

The machine moved 12 yards of dirt per hour, with an average one-way haul of 150 feet, giving a cost of 7.2 cents per cu. yd. Including depreciation and repairs, the cost would be about 14 cents per yard. This work involved removing dirt that had slid in from a cut 25 feet deep, completely filling the side ditches and reaching almost to the ties, and it was performed without slow orders or interruption of traffic. Several small trees had to be removed and small pools of water made the clay sticky and difficult to handle.

Front End Loader Scoop Replaced with Bull Dozer.

### AIR COMPRESSORS

Air compressors mounted on track type tractors find a wide range of usefulness in maintenance of way work. There are a number of models available which can be readily attached to tractors of the size generally used in maintenance of way work without interfering with any of the other functions of the tractor nor affecting its stability against overturning. Power for operating the compressor is taken from the engine of the tractor.

Compressors are available in rated capacities ranging from 140 to 320 c.f.m. piston displacement and pressures of 90 lb. to 100 lb. at a speed of about 750 r.p.m. Greater capacity may be obtained by mounting two compressor units on the same tractor, which can be done with the larger sizes of tractors.

Front End Loader—Loading Snow into a Gondola Car.

Front End Loader Hinged Type—Loading.

Front End Loader Hinged Type—  
Dumping

The machine can be used for any of the jobs for which compressed air is adapted, such as spray painting; tamping ties; breaking up concrete and pavement; rock drilling; driving rivets; nut running; sand blasting; cement gun work; operating small cutting, boring, drilling, grinding and hammer tools; operating air lifts and jacks; charging train lines, etc. The smaller sizes will operate either

- 1 rock drill (heavy duty)
- 4 clay diggers
- 2 sheeting drivers
- 4 riveting hammers
- 5 wire brushing machines—light duty

- 2 wire brushing machines—heavy duty
- 2 paving breakers
- 4 backfill or tie tampers
- 4 caulking hammers
- 2 concrete surface grinders

or other tools in proportion.

Front End Loader Cleaning Out a Side Ditch.

Air Compressor Mounted on Track Type Tractor. Framing Bridge Timbers.

The outfit has the advantage of easy and ready mobility which reduces the length of hose or pipe required, enables the machine to be placed on the windward side of dusty operations, such as concrete breaking or sand blasting, and permits it to be moved quickly from one job to another without having to stop the compressor. At the same time, the attachment does not interfere with the tractor's towing ability which can be used to good advantage on many jobs.

Air Compressor Mounted on a Track Type Tractor Operating a Spray Painting Outfit.  
"Caterpillar" Twenty Equipped with Davey Air Compressor Running Paint Spraying Machine.

Air Compressor Mounted on a Track Type Tractor Operating Tie Tampers.

On one road a model 25 track type tractor, equipped with a 140 cu. ft. capacity compressor, operated four tie tampers with  $4\frac{1}{2}$  inch tamping faces, working a 3 inch raise in pit run gravel. The cost per hour was as follows:

|                                |        |
|--------------------------------|--------|
| Gasoline—2.8 gal. @ 0.10 ..... | \$0.28 |
| Oil and grease .....           | 0.07   |
| Operator .....                 | 0.76   |
| Total operating cost .....     | \$1.11 |

On another job of constructing a water station and moving a steel water tank, a similar outfit was used with an operating cost of \$1.04 per hour. Other roads report satisfactory results from the use of similar units.

## PART II

### SCORING SHEET FOR TRACK TYPE TRACTORS

This scoring sheet is presented in the hope that it will provide a basis or outline for the logical and systematic comparison of tractors of various makes and aid the engineer in the selection of a particular machine for purchase.

An effort has been made to include all features which will influence such a selection and to assign to each of these features a value which will represent 100 per cent fulfillment of that feature. Additional items may suggest themselves on certain roads and different engineers may wish to vary the values given to conform to their individual experience or their special conditions and problems. A discussion of the items and their values would lead to endless opinions and the Committee, therefore, offers the scoring sheet rather as an outline which can be used for preparing a sheet to meet special conditions.

The method of using the sheet is simple. A separate sheet is made for every tractor under consideration and on that sheet the tractor is given a rating on each item, the value originally assigned to the item being considered 100 per cent. When the rating has been completed the sheet is added and the tractor receiving the highest total score should be selected.

|                                                                  |     |

### Appendix E

#### (11) USE OF WEED DESTROYING EQUIPMENT, INCLUDING HORSE-DRAWN AND POWER MOWERS OPERATING BOTH ON AND OFF THE TRACK

Fred Zavatkay, Chairman, Sub-Committee; J. J. Davis, R. J. Gammie, R. C. Haynes, G. W. Hunt, E. A. Johnson, Jack Largent, T. M. Pittman, J. G. Sheldrick, Harry Slabotsky, J. B. Trenholm.

Vegetation growing on the right-of-way of the railroad is objectionable for several reasons. It increases maintenance expenses, spreads fires, obstructs view, and frequently interferes with communication lines and sometimes causes delays to train movement.

The removal and prevention of vegetation growing on the roadbed reduces maintenance expenses and affords better drainage for ballast, prolongs the life of ties, eliminates slipping of locomotives on account of crushed vegetation on rails.

"Manual of Weeds," by G. A. Eljiva, MacMillan 14-18393, with description of all of the most pernicious and troublesome plants in the United States and Canada, their habits of growth and distribution, accounts for 2263 different species including a list of 64 plants that are distinctly poisonous or otherwise harmful to animal life.

Many of these weeds can be found on the right-of-way. The most troublesome are Bermuda grass, Johnson grass, crab grass, sage, horsetail, bindweed and sweet clover.

#### Destroying Weeds by Hand Method

The average cost of a single removal of weeds from roadbed by hand varies widely and in some localities may be as high as \$125.00 per mile.

On some railroads, cutting the right-of-way once a year has been found sufficient usually to keep it in fair condition, but on others particularly in the South, weeds grow so rapidly that it is necessary to remove them twice a year. The first cutting is done late in the spring, and the second early in the fall. On account of the effectiveness being only temporary, it is necessary to repeat the performance year after year.

Concentrated effort has been directed toward the development of equipment to perform this work satisfactorily and more economically. Methods employed to a large extent have been with the use of horse-drawn plows or mowing machines and men with scythes, as well as with shovels for grassing between ties.

### Various Devices Used

Many devices have been tried on railroads with view to eliminating hand weeding. The use of chemicals to kill weeds has been effectively carried out, depending on the density and character of vegetation and varying considerably as to the cost per mile. Superheated steam, revolving wire brushes, track mowing machines, discers and weed burners have been employed with various measures of effectiveness and efficiency.

### Chemical Weed Killer

Experience with the use of chemical weed killer, over a period of approximately fourteen years, would indicate that the treatment has a sterilizing effect on the ballast, although the effect is cumulative only to a certain point.

The chemicals are effective in retarding and preventing the growth of biennials and perennials to a certain extent, but from experiences they have little effect on hardy perennials such as Johnson and Bermuda grass, especially in the South.

The application of chemicals is usually confined to the ballast section or roadbed and little effort is made to kill the growth outside these limits.

A typical chemical weed killer train usually consists of, from head to rear, in order listed:

- 1 flat car, half house and half shed, to which sprinklers are attached and on which are all the control valves and meter;

- One or more steel tank cars fitted with special piping to distribute chemical to the spray car;

- 1 converted coach used as living car for a crew of three men. One part of coach partitioned off for air compressor;

- 1 locomotive and 1 caboose.

Each of the tank cars is filled with chemical and water in the required proportion and kept agitated with air. The outfit is pushed forward, thereby giving the operators clear view of the track to be sprayed. Approximately the same arrangement can be used when applying oil for killing weeds.

### Non-Poisonous Powder (*Atlacide*)

This chemical has given very satisfactory results. It is applied by hand and is particularly valuable to signal departments in sprinkling around signal poles and other signal apparatus. It is also useful in destroying the Canadian thistle.

The material is furnished in 50-lb. drums with a number of 3½ lb. tin containers with perforated covers for sprinkling the material over the spots to be treated. A knapsack hand-operated duster or sprayer is also used for applying the powder over weed areas of moderate size. The knapsack duster weighs 16 lb. when empty and has a capacity for 25 lb. of powder. It can be used by one man and is useful in isolated patches of weeds or over very large areas.

If the powder becomes caked after absorbing moisture when a drum has been opened, thus preventing proper dusting, the material may be dissolved in water and applied with a whitewash spraying outfit or sprinkling can.

## Steam Weed Destroyer

This method produces good results, serving the purpose of cleaning by hand and at much lower cost. The steam treatment withers the top of the vegetation, but does not kill the roots.

## Mowing Machines

Track mowing machines, self-propelled and non-self-propelled are used extensively with satisfactory results, considering the limitations of such machines. They are used to cut the swath, usually 7 feet to 11 feet beyond end of ties. Where the obstructions are not numerous, these machines can be used to best advantage. Horse-drawn and tractor-drawn mowers are used around station grounds and other portions of right-of-way.

## Ballast Discers

Ballast discers give best results when the track is fully ballasted with small gravel, burnt gumbo, or chats and at least 8 inches under ties. It is not very effective in its use on track ballasted with crushed stone of 2-inch or  $2\frac{1}{2}$ -inch size or larger of quality which closely packs or cements in track. Where conditions are right, satisfactory results are obtained, the ballast shoulder is loosened up, and the vegetation can be easily removed by section forces and better drainage afforded.

## Weed Burners

The development of weed burning machines was carried out in a large measure from the experience of the Yazoo & Mississippi Valley Railroad. While these machines proved to be very efficient labor-saving devices and more economical than any other method of destroying weeds during their early development, weed burning machines with many improvements developed in the past six or seven years have resulted in greater efficiency of operation. Two different makes are used now most extensively, the Fairmont and the Woolery.

Most satisfactory results can be obtained by commencing operations about May 1st, and operating the machine at such speed as will give the vegetation a thorough scorching, repeating the performance within sixty days. With such operation it is possible to keep the entire ballast section practically clean during growing season.

Reports indicate fire damage to cross-ties and other structures is experienced infrequently, but some claims of relatively small amounts have had to be settled by Claims Department on different lines for burning pastures and woods. However, at least one railroad has experienced so much trouble with fire damage that the use of the equipment was abandoned. Fire fighting equipment usually consists of section gang with motor car and trailer following behind the weed burner. On the trailer car a water tank or several barrels containing approximately 400 gallons and a small gas engine water pump fitted up so tank or barrels can be filled from streams adjacent to the track. The pump is also used to provide pressure in two lines of ordinary garden hose equipped with nozzles. This outfit, although somewhat crude, is very effective and develops a considerable saving over handling the water with buckets.

There is considerable variation in the performance of the different machines even of the same make on the same territory and a wider difference between performance of machines on extreme Northern and Southern lines.

A small type burner has recently been developed to be handled by motor car section crew; it is designed especially for branch line service or for the burning of passing, side and yard tracks.

Reports from railroads to whom inquiry was directed indicate weed destroying equipment and cost data for operation as follows:

(13) TRACK WELDING EQUIPMENT (a) OXY-ACETYLENE;  
(b) ELECTRIC ARC

J. M. Trissal, Chairman, Sub-Committee; M. D. Bowen, Walter Constance, J. J. Davis, Wm. Elmer, C. L. Fero, R. J. Gammie, Paul Hamilton, F. W. Hillman, Harry Homans, Jack Largent, E. H. Ness, J. G. Sheldrick, L. J. Turner, G. R. Westcott, Fred Zavatkay.

The Maintenance of Way Department of a railway may employ welding for building up rail ends, repairing frogs and switches, and welding bridge members and structural steel work. As the type and requirements of equipment necessary to properly handle the welding of bridge members and structural steel is determined by the particular conditions involved, they will not be discussed in this report.

The conditions involving selection of proper equipment for building up rail ends and repairing frogs and switches are essentially the same on all railroads and will be discussed in this report.

Two distinct processes of welding are employed in handling this work, namely, the oxy-acetylene torch and the electric arc. The oxy-acetylene torch is generally considered preferable for cutting purposes, whereas the electric arc is the only method that has been successfully employed in welding manganese. The relative economies of the two methods of welding are subject to considerable deviation and depend largely upon the organization and methods of operation. The following facts, however, are generally applicable in studying the difference in cost of work performed by the two methods.

1. Oxy-acetylene welding requires less equipment and lower initial investment than does electric welding.
2. Due to limitations of capacity of electric welding equipment in general use, the number of welders that can be conveniently used at one location is larger with oxy-acetylene welding than with electric welding.
3. The welding equipment necessary for oxy-acetylene welding is much more portable than is equipment for electric welding.
4. Oxygen and gas required for oxy-acetylene welding are more expensive than gasoline and oil necessary to drive portable electric welding machinery or electrical energy for driving motor generator electric welding machinery.
5. To obtain the maximum economy from electric welding equipment, it must be portable and kept in service as nearly continuously as practicable.

The organization and methods employed in oxy-acetylene welding have been developed over a period of years and the process is in extensive use for repairing carbon steel frogs and switches, butt welding joints and building up battered rail ends. Torches and gas regulators have been greatly improved, and for the latter work one of the Eastern roads is now using double tip flame. It is claimed that the speed of the depositing metal is thus nearly doubled, and the heat does not have time to penetrate so deeply into the rail head. They hope to develop a three-tip torch in the near future to still further increase the speed and reduce the cost. The usual round welding rod becomes a flat strip for this work.

On some roads, in building up battered rail ends, it is customary, after heating the rails with the torch, to drive the metal in from the sides, which raises the surface and reduces the amount of metal to be added. On some roads the welders beat down the applied new metal with a hand hammer, using a straight edge from time to time to test the evenness of the work. On other roads a helper strikes a flatter held by the welder, and sometimes the welder lays down the torch and strikes the flatter held in his left hand with a heavy hammer wielded by his right.

There are two general types of electric welding equipment, namely, the alternating current type and the direct current type. The alternating current type of welding overcomes to a large extent the objection to electric welding equipment not being portable. Electrical energy is generated at 440 volts or higher and is then transmitted over relatively small sized cables for a considerable distance where it is transformed to the voltage required for welding. In this manner it is possible for one welding machine at single setting to supply energy necessary for welding over a section of track a mile long. In this type of equipment, however, the cost and maintenance of cables are considerable and there is always the problem of possible theft of cables unless a watchman is left with the machine at all times. Also it is generally considered that welding with alternating current is more difficult and not as satisfactory as welding with direct current. When 440 volt potential is to be used for the transmission of energy, through cables which lie along the right-of-way and are connected and disconnected by men who are, in all probability, not electricians, the problem of personal hazard becomes one of the most serious objections to this method of welding.

In direct current welding the current is supplied to the arc by means of relatively large cables, usually 4/0. There are many machines now in use, of constant voltage type, having cables up to 1500 feet in length but as the loss of energy involved is considerable, a later trend is toward cable lengths not exceeding 300 or 400 feet, used with a variable voltage machine, thus reducing the energy loss, but introducing the necessity of frequently changing the location of the machines.

Electric welding machines in the past have commonly been mounted on portable trucks either self-propelled or non-self-propelled, on standard gage with crosswise trucks for removing the machine from the track.

To overcome the heavy energy loss inherent in the use of long cables and at the same time avoid labor and time in making frequent changes in location of machine, a recent development is the practice of mounting the welding generator on a tractor which is capable of moving along the right-of-way and over bridges and culverts to any desired location.

Fig. 1 and 2 show the type employed on the Lehigh Valley, where a 300 ampere welding generator is mounted inside of a tank type tractor which is 15 ft. long, 32 in. wide and 37 in. high. The size of the tractor was determined by the conditions to be met when running along the side of the tracks through various cuts and on fills. The motive power for operating the tractor is supplied from a  $7\frac{1}{2}$  KW auxiliary generator which supplies electrical energy to two 5 HP. motors which are geared directly to the tractor tracks. When the tractor is not being propelled along the right-of-way the output of this  $7\frac{1}{2}$  KW generator is available for driving grinders and other auxiliary equipment. The 300 ampere welding generator is driven from a 65 HP. gasoline engine and supplies ample current for the operation of one arc.

The welding and ground cables employed with this particular machine are of 3/0 size, each 150 feet long, which permit the machine to supply energy for welding 12 joints in each track without moving the machine when work is being performed on 39-ft. rails.

The auxiliary generator enables the use of electrically driven grinders which are used for surface grinding and cross-slotting of rail ends.

With this particular equipment a force of one welder, one grinder operator, one laborer and one flagman is employed. The grinder operator moves the tractor when it is necessary and sees that proper voltage and current values are obtained from the generators for the operation of welding and grinding equipment.

FIG. 1.—Tank Type Tractor with Arc in Operation.

FIG. 2.—Tank Type Tractor Mounting Loading Platform.

Fig. 3 and 4 shows the type of tractor mounted welding equipment used on the DL&W. This equipment consists of a 300 ampere welding generator, belt driven from a 25 HP. gasoline engine which also furnishes power for the propulsion of the track type tractor upon which the generator is mounted. One hundred and fifty feet lengths of 4/0 cable are used for welding and ground leads which permit the welding of approximately 12 joints in each track without the movement of the tractor.

FIG. 3.—Method of Mounting Welding Equipment on Track Type Tractor.

FIG. 4.—Track Type Tractor with Arc and Grinder in Operation.

In this particular equipment there is no generator for supplying electrical energy for accessory operation and grinding is handled with gasoline driven surface and cross grinders. Two of these tractor welders are operated at the same location and the force employed consists of one foreman, two welders, one grinder and one flagman.

The width of the machine is  $58\frac{1}{2}$  inches but the cuts and fills encountered on the DL&W will enable the machine to operate successfully along the side of the right-of-way without interfering with train movements.

Fig. 5 shows the type of tractor mounting employed on the Illinois Central's Chicago Terminal where the welder is used exclusively on frog and switch work. In this equip-

ment a 300 ampere machine is mounted on a truck and equipped with 4/0 welding and ground cables 150 feet long. Due to the fact that all frogs and switches on the Chicago Terminal are accessible to automobile roads, this equipment has proved entirely satisfactory. The truck type mounting greatly facilitates the movement from point to point when they are some distance apart. However, use of this equipment has a limited field as it can not be used with any great degree of success on rail end work and must be used on a terminal so located that the frogs and switches to be welded are accessible to automobiles. Other roads in various parts of the country have made use of similar equipment.

Fig. 6 shows type of mounting employed on the C&O where the machine is moved from one general location to another by loading it on a specially designed trailer car and pulling it along the track. This equipment consists simply of a 200 ampere gasoline driven machine mounted on pneumatic tired wheels, which can be readily loaded on the

FIG. 5.—300 Ampere Welder Mounted on Automobile Truck.

FIG. 6.—Electric Welder with Rubber Tires Mounted on Specially Designed Trailed Car.

trailer. The use of pneumatic tired wheels permits of easy movement over the rails and along right-of-way for joint welding around yards. Two 3/0 cables 125 feet in length, are sufficient for the machine to handle 9 joints in each track from one location.

Various other methods of mounting of welding equipment have been developed and unquestionably more will be developed in the future but it is believed that the results on the roads mentioned above indicate a high degree of portability can be obtained by various methods of mounting of direct current welding equipment.

In all classes of welding equipment it is essential that the electric arc be stable and relatively flexible. In order to do this it is necessary that a constant voltage be maintained and current surges eliminated as far as practicable. If the arc should be extinguished the voltage should immediately come back to its full open circuit value in order to facilitate the re-striking of the arc.

These characteristics are obtained in various ways in the various machines and a study of the characteristics of the individual machine will illustrate accurately wherein any differences may lie.

Obviously the most satisfactory machine will be the one wherein the most universal characteristics are obtained with the least possible adjustment, and it should be borne in mind that the operators of the welding equipment, in all probability, are not electricians and the fewer adjustments it is necessary for them to make, the more satisfactory will be the operation.

The types of connections which are made to the welding equipment vary greatly with the various models and the connector which makes the best contact in the easiest manner with the maximum of safety is the connector which is best adapted to this service. It is essential that good contact be maintained in all cases as a considerable drop in voltage will exist due to any poor connection.

Length of cables involved is of considerable importance as too long a cable will bring about excessive voltage drop and cause poor welding conditions as well as overloading of the machine. There is set forth below a tabulation indicating what the voltage drop will be with various sizes and lengths of cable with various currents flowing through them.

VOLTAGE DROP WITH VARIOUS CURRENTS (77° FAHR.)

National Electrical Code *continuous* current carrying capacities.

3/0 cables 175 amps.

4/0 cables 225 amps.

It is the belief of the Committee that the subject of equipment for handling electric arc welding in the Maintenance of Way Departments of railroads is a very important

one and that it will become of greater importance in the near future. The Committee plans to obtain definite operating statistics so that next year its report will contain information relative to both the oxy-acetylene and the electric arc method of building up rail ends and performing frog and switch welding.

### Appendix G

#### (15) THE USE AND MAINTENANCE OF PAINT SPRAYING EQUIPMENT WITH OUTLINE OF TYPICAL ORGANIZATION FOR VARIOUS CLASSES OF WORK

N. M. Trapnell, Chairman, Sub-Committee; W. A. Batey, G. J. Ermentrout, Robert Faries, C. L. Fero, Paul Hamilton, J. S. Huntoon, E. H. Mills, T. M. Pittman, Harry Slabotsky, H. W. Stetson, J. B. Trenholm.

The present report deals with the results of a test of the application of bridge paint by means of the spray gun and the hand brush, made by an Eastern railroad in February, 1933. The test was made primarily to determine the comparative qualities of certain bridge paints. However, much of the data collected is of value in comparing the two methods of application.

The test was made on a deck plate-girder bridge, using six different bridge paints and six primers. In order to conduct the test with equal fairness to all paints used, they were all applied to the same side of the bridge, but on different spans, and were all subject as nearly as possible to the same general conditions.

The first part of the test was made with paint spraying equipment, the same well-known make of spray gun having been used exclusively. The second part of the test was conducted with hand brush application. The spray application was made on the north side of the bridge, beginning at the west end and working east. The brush application was also made on the north side, east of the spray application. In both cases one gallon of each manufacturer's primer was used, and one gallon of each manufacturer's "Black" was next applied over its own primer.

The data recorded for each paint and primer included the weight per gallon, cost per gallon, area covered, man-hours per gallon, man-hours per 100 square feet, cost per 100 square feet, air pressure used, atmospheric temperature, ease of application, general appearance, and weather conditions at the time of application. Most of the detailed data recorded is given in the supplementary table.

Only the actual time consumed in applying the paint was recorded, because, as stated previously, the purpose of this test was to determine the comparative qualities of different paints, and a fair comparison of cost would be impossible if the time consumed in cleaning, moving scaffolding and delays not caused by the paint itself, were charged against it.

A summary of the averages contained in the supplementary table of data, showing a comparison between the two methods of application, is as follows:

|                                         | <i>Primers</i> |              | <i>Paints</i> |              |
|-----------------------------------------|----------------|--------------|---------------|--------------|
|                                         | <i>Spray</i>   | <i>Brush</i> | <i>Spray</i>  | <i>Brush</i> |
| Avg. weight per gallon—lb. ....         | 14.5           | 14.5         | 8.8           | 8.8          |
| " cost per gallon .....                 | \$1.79         | \$1.79       | \$1.31        | \$1.31       |
| " area covered—sq. ft. per gallon ..... | 398.17         | 385.03       | 230.01        | 436.17       |
| " man-hrs. per gallon .....             | .185           | 1.483        | .193          | 2.165        |
| " " " 100 sq. ft. ....                  | .052           | .396         | .091          | .508         |
| " cost per 100 sq. ft. ....             | \$ .453        | \$ .722      | \$ .724       | \$ .625      |
| " air pressure—pounds .....             | 23             | ...          | 26            | ...          |
| " atmospheric temperature .....         | 26°            | 37°          | 23°           | 33°          |

The primers used varied in weight from 11.1 to 18.1 lb. per gallon, and in price from \$1.20 to \$3.00 per gallon. The paints used varied in weight from 7.9 to 9.7 lb. per gallon, and in price from \$.74 to \$1.85 per gallon. It is therefore considered that the averages shown in the foregoing table are fairly accurate as regards the effect of quality on area covered and cost of application.

The increase or decrease in area covered, labor to apply, and cost of application by the spray method compared to the hand brush method, is as follows:

|                                                     | <i>Primers</i> |                 | <i>Paints</i> |                 |
|-----------------------------------------------------|----------------|-----------------|---------------|-----------------|
|                                                     | <i>Amount</i>  | <i>Per Cent</i> | <i>Amount</i> | <i>Per Cent</i> |
| Difference in area covered—sq. ft. per gallon ..... | 131.4 inc.     | 34.2% inc.      | 206.16 dec.   | 42.2% dec.      |
| Difference in man-hours per gallon ....             | 1.298 dec.     | 87.6% dec.      | 1.972 dec.    | 91.4% dec.      |
| Difference in man-hours per 100 sq. ft. ....        | .344 dec.      | 86.9% dec.      | .417 dec.     | 82.3% dec.      |
| Difference in cost per 100 sq. ft. ....             | \$.269 dec.    | 36.2% dec.      | \$.099 inc.   | 15.9% inc.      |

It will be noted that, in the case of the primers, there is no question of the economy of the spray method. The area covered is 34 per cent greater, the time required for application is 87 per cent less, and the cost of labor and material is 36 per cent less, than for the brush method.

However, in the case of the paints, the result appears to be somewhat different. Although the time required for application is 82 per cent to 91 per cent less, the total cost of application per 100 sq. ft., including labor and material, is 16 per cent greater for the spray method than for brush painting. This is accounted for by the fact that the area per gallon covered with brush application is 42 per cent greater than that covered with the spray, and therefore, the amount of paint applied per 100 sq. ft. is 42 per cent less.

The decrease in the amount of paint applied per unit area with the hand brush method indicates a considerably thinner paint film than that obtained with the spray method. Also, the character of the surface of the brush film is not as smooth and uniform as that of the spray film, due to the minute grooves made by the bristles of the brush. In view of these facts, it is highly probable that the spray film will prove to be the most durable and may be more economical in the end than the brush film, although the cost of application per unit area is 16 per cent greater.

It is concluded that the results of this test demonstrate fairly conclusively the economy of spray painting as compared to the hand brush method, when applied to large surfaces. It should be borne in mind that the weather conditions during the test were rather severe, with a strong wind blowing most of the time. This tends to increase the paint consumption with the spray method, as much of it is blown away and lost.

The cost of cleaning the surfaces to be painted was practically the same for both methods of application. Also, there was little difference in the cost of erecting and moving scaffolding. Where extension guns are used the cost of handling scaffolding is considerably less for spray painting than for hand brush painting. The only items of cost incident to spray painting which do not obtain with brush painting are the setting up, maintenance, and operation of the air compressor and maintenance of the paint-spraying equipment. However, these are more than offset by the saving in man-hours on large jobs.

It is recommended that the present report be received as supplementary information to the report submitted by this Sub-Committee in 1931.

TABULATED RESULTS OF TEST OF BRIDGE PAINT APPLICATION

## Appendix H

## HAZARDS OF SPRAY PAINTING

There has always been a certain hazard to health in the handling of paints and painting materials regardless of whether it was applied by brush or spray. Poisoning due to lead contained in paints, also to the thinners used has been recognized as a hazard to health long before air was used. A review of the poisonous ingredients in paints, lacquers, enamels, etc. indicates that the most serious hazards are from lead which is a constituent of many paints, benzol which has been used extensively as a thinner and silica used almost altogether in connection with spraying enameled ware.

In the early days of spray painting the theory was advanced that the fine diffusion of paint materials by the spray was such that inhalation resulted in great danger to the operator and in some cases where paint spraying equipment was first used indoors without the use of properly ventilated booths this theory seemed to be borne out in fact. While no statistics are available it appears that insofar as outdoor painting is concerned the spray gun offers no greater hazard than the use of the brush because the natural air currents are adequate to dispose of the fumes. Where spray painting is done indoors with paints containing lead or benzol there is a possible health hazard unless proper ventilation is provided. The National Safety Council has conducted what was probably the most extensive investigation ever made as to the probable hazards of spray painting and a means of overcoming them. A comprehensive report of that committee was published by the National Safety Council in 1927. A very brief summary of the findings of the committee follows:

It was determined that benzol poisoning might occur from the continual use of the material as a solvent or thinner in painting materials either through the application of brush or spray. It was further found that the hazard of benzol poisoning could be eliminated through the installation of efficient air conditioning equipment in rooms where painting was carried on. It was also found that the hazard of poisoning from benzol could be very materially reduced by the use of ordinary masks or respirators, or eliminated entirely by the use of especially designed respirators. Their investigation determined that all cases of benzol poisoning were confined to workmen engaged in interior painting.

The comments in regard to hazards of lead poisoning are practically the same as those with reference to benzol poisoning. Also, the same methods of eliminating the hazards are recommended, and as with the benzol poisoning all workmen who showed any trace of lead poisoning were engaged in interior painting.

It is apparent from the National Safety Council's investigation that there are three sources of health hazards encountered in spray painting, namely, inhalation of benzol fumes, lead particles or silica dust.

It is apparent from this report that there is but little danger from the benzol fumes or lead where painting is done outdoors. Such fumes are quickly dissipated or diluted by contact with fresh air. Lead poisoning occurs through continuous inhaling of lead particles and not through the application on the hands, face or body, as there is but little danger of lead poisoning absorbed from paint coming in contact with the skin. Silicosis due to inhalation of dust particles of silica rarely occurs in railroad work as silica is probably not present in paints used on railroad buildings of other structures, the only hazard from silica being in sand blasting. When this work is done outdoors, however, such hazard is practically negligible.

The Monthly Labor Review (May, 1929) of the Bureau of Labor Statistics, United States Department of Labor, has the following comments to make in regard to hazards of poisoning from the use of paints or coatings:

"Poisoning or disability from the use of paint or coatings arises mainly from three sources; namely, from the use of lead and its compounds, from benzol, and from siliceous materials.

"The lead compounds are used in the form of lead chromates in pigments, and carbonates, sulphates, and sulphides as paint bases. Poisoning from lead compounds in paints may occur from:

- (a) Inhalation of dust from sandpapering one coat of paint preparatory to applying another.
- (b) Entry of dust into either the respiratory or digestive system from mixing dry white lead with oil.
- (c) Inhaling fumes from burning off old paint.
- (d) Inhaling dust arising from lead paint dried on overalls and drip cloths.
- (e) Breathing of lead paints nebulized by spraying and suspended in the air, which may find their way into both the alimentary canal and the respiratory system.
- (f) Using glazing putty containing lead compounds.

"Of these six possibilities the result may be either contamination of food by unwashed hands, entrance of lead into the alimentary canal by placing objects in the mouth while working with lead compounds, or the direct inhalation of lead in dust form into the lungs where it can be directly absorbed into the blood. In spray painting the last named type of absorption is the most likely, and authorities state that this type produces the greatest toxic effect because the lead is absorbed directly by the blood without having to go through the liver, while lead which passes through the alimentary canal does go to the liver and much of it is thrown off through the excretory system.

"Benzol poisoning results from the continual breathing of benzol fumes. These fumes can not be removed from the air by any method not involving chemical means. It has been stated that a worker continually breathing air containing 100 parts or more of benzol in 1,000,000 parts of air is working under a substantial hazard. This is due to the fact that benzol taken into the system forms a chemical combination with the body tissues, especially the marrow of the bones, where it affects the formation of red blood corpuscles. The National Safety Council's report on benzol (May, 1926) states that 'generally cases of acute poisoning from inhalation are either rapidly fatal or respond favorably to treatment with more or less complete recovery within a short period. \* \* \* In chronic benzol poisoning we find a wholly different picture. The onset is insidious, the early symptoms are generally overlooked, and it is not until the condition becomes relatively grave that it receives medical attention.'"

Silica, as used in various enamels and glazes, also presents certain dangers. Breathing sufficient siliceous material causes what is known as silicosis, an ailment resulting from the accumulation of considerable quantities of insoluble dust material in the lungs. This dust is not absorbed by the blood and its presence causes irritation and later what is termed "fibrosis."

The following measures are suggested for overcoming dangerous practices in the use of paints:

- (a) Greasing unprotected portions of the body, to make any material collecting thereon easily removable.
- (b) Thorough washing and the brushing of the finger nails, as well as avoiding the habit of placing anything in the mouth during work hours.
- (c) Protection of food and of street clothing from dust and spray.
- (d) Cleanliness of working clothes.
- (e) Teaching employees of the proper use of the gun.

- (f) Equal protection of all employees who are working within 30 feet of the spray gun where no direct exhaust is available.
- (g) Wet sanding instead of dry sanding wherever possible.
- (h) Reduction of the pressure on pressure containers to the lowest point consistent with speed of application required.
- (i) Reduction of the pressure used to break up the material to the lowest point consistent with the nebulization required.
- (j) Careful use of the gun at the proper distance from the work.
- (k) Use of nontoxic materials of nonirritating character wherever possible.

State regulations regarding spray painting, also taken from The Monthly Labor Review, follow:

"Massachusetts, Michigan, and Wisconsin control the process of spray coating by a code of special rules and regulations, while California, New York, and Pennsylvania have tentative codes of rules and regulations. In New York the code is still in the hands of an advisory committee; in California and Pennsylvania the codes have been submitted to the public but have not yet been approved by proper authority and therefore do not now have the force of law.

"Illinois, New Jersey, and Ohio have comprehensive laws dealing in considerable detail with means of protecting the health and welfare of workmen, and which apply generally to any hazardous process or condition in manufacturing plants. These laws guide inspection of spraying equipment and conditions in the three states.

"In Maryland and Wyoming, and in the United States Congress, bills are pending to regulate the process of spray painting.

"The Colorado Department of Labor has formulated a set of rules and requirements as a guide for factory inspectors in certifying spray-painting equipment in the State.

"Connecticut, Delaware, Iowa, Maine, Minnesota, Missouri, New Hampshire, Rhode Island, Washington, and West Virginia have general statutes concerning ventilation or sanitation which would probably apply to any spray painting where the materials used contained lead, benzol, or other toxic material.

"In Ohio the industrial commission is empowered to supervise the life, health, safety, and welfare of employees. Under this authority, the commission has issued supplementary rules for the guidance of factory inspectors in making or issuing specific orders when inspecting spray-coating equipment. These rules for the inspectors operate only as a guide to the inspector and do not in any sense apply as law to spray operations in establishments in the State. When the inspector issues a specific order to the employer, however, the order has the effect of law. In Tennessee the general law covering ventilation is pointed out by the State department of labor as its only recourse at present in dealing with the problems of spraying paint. The State has made some efforts toward the formulation of special rules and regulations applying to spray painting, but no definite results have been obtained up to this time. In Utah a similar condition exists. The industrial commission of that State points out that the provision of their workmen's compensation act which obligates the employer to do what is reasonably necessary to protect the life, health, safety, and welfare of workmen is the only provision at present covering in any way the subject of spray painting.

All of the statutes mentioned above appear in Bulletin No. 370 of the United States Bureau of Labor Statistics. The Bulletin, however, does not contain special rules and regulations which have the force of law.

## Appendix I

(16) ORGANIZATION FOR THE USE AND MAINTENANCE OF BALLAST CLEANING MACHINES AND CONDITIONS UNDER WHICH EACH PARTICULAR TYPE MAY BE USED (INCLUDING MOLES, SCREENS, LOCOMOTIVE CRANES, AND PLOWS USED IN CONJUNCTION WITH BALLAST DISCERS)

Wm. Elmer, Chairman, Sub-Committee; Walter Constance, W. O. Cudworth, J. F. Donovan, Robert Faries, F. S. Hewes, G. W. Hunt, J. S. Huntoon, C. H. Morse, Fred Zavatkay.

Since our report in Vol. 33 of the Proceedings, page 183, there has been completed and placed in service a two-sided ballast cleaning machine which operates on a border and the intertrack space, or on two intertrack spaces simultaneously, as desired. Fig. 1 shows the cleaning unit, consisting of a 65-ft. 105-ton all-steel gas-electric car behind which are coupled two standard 50-ft. flat cars equipped with dirt-disposal machinery. Any kind of locomotive of sufficient capacity may be used for pulling the cleaner. A fourth unit required is some sort of car for supplies, spare parts, welding and cutting apparatus, electric and compressed air drills, etc., for quickly making emergency repairs on the job.

FIG. 1.

The ballast cleaner frame and structure (Fig. 2) are electrically welded, mounted on two 4-wheel trucks spaced 54 ft. center to center. In operation, the locomotive takes position with its brakes set, about 500 ft. ahead of the cleaner, which hauls itself forward by reeling up a steel cable attached to the locomotive.

Rock ballast is picked up on each side from the border or center ditch as the case may be, and screened by two cleaner boxes 30 inches wide, 7 ft. high and 21 ft. long. These 15-ton boxes are hung in wells midway on each side of the machine, within standard A.R.A. clearance. To clean ballast they are moved out and in, lowered and raised, with hydraulic cylinders actuated by oil at 300 lb. pressure per square inch.

Each cleaner box has two vertical in-gathering wings 30 inches high, mounted on the front end flush with the bottom of the box. Each wing is separately controlled by a hydraulic cylinder. The opening between wings can be varied from 36 inches to approximately 60 inches. Thus all ballast between ties of adjacent tracks where tie ends are not less than 38 inches or more than 64 inches apart, can be taken into the cleaner boxes. Either wing can be moved in or out to maintain correct distance from short or long ties, without stopping.

FIG. 2.

All foul ballast is removed from the tie ends, and about one inch is undercut below the ties, by a "step-shaped" projection in the lower wing section which is furnished according to individual railroad requirements. This insures good clean ballast surrounding and underlying the ends of ties after the machine passes.

Ballast is cleaned by passing up an incline over manganese steel grates or screens. It is moved by a manganese steel conveyor chain with flights or paddles every 12 inches, run at a speed of 150 ft. per minute by a 50 HP. electric motor. The flights rub and roll the foul ballast over the grates with a jerky, vibratory action which shakes the dirt loose and drops it through the screen back on the roadbed.

This loose dirt on the roadbed is plowed level, compacted, and the excess dirt picked up by a conveyor which delivers it at the rear of the cleaner box to a 20-inch belt conveyor which carries it into a hopper on the forward end of the 2-car dirt unit.

The cleaned ballast is deposited on the prepared roadbed surface and machine-shaped or dressed to the desired contour, whether center ditch or border.

The two flat cars are fitted with steel-lined 8-ft. walls and together can store about 150 cu. yds. of dirt, enough for 1500 to 4000 ft. of track if cleaning on both sides. Dirt is stored only when working in cuts or other places where it cannot be thrown over the roadbed shoulder.

Most of the time, dirt falls through the hopper to a lower level, upon a 36-inch belt conveyor 22-ft. long, which may be swung out on either side of the car at right angles, passing the dirt across one adjoining track and wasting it over the roadway bank.

Where there is no suitable dumping place, a two-way dragline scraper hauls the dirt back into the cars. When full, the cleaner moves ahead to the nearest spot where dumping is permissible, and starts cleaning ballast while the dirt cars are discharging, thus avoiding idle time while dumping.

The 36-inch discharge conveyor has ample capacity to handle both the dirt from the cleaner and that brought out of the dirt cars by the reversed dragline scraper. When the cars are emptied the cleaner train backs up and resumes cleaning and storing dirt at the first scene of operations.

The ballast cleaning car has a total of 435 HP. in gasoline engines, distributed as follows: 175 HP. to generate current for 11 electric motors, one of 30 HP. operating the 18 oil-pressure cylinders; 120 HP. for the towing hoist; 110 HP. for the 2-drum dragline scraper.

During the past summer this machine, while working on a 4-track section of a busy Eastern railroad cleaned in three weeks, working two 8-hour shifts a day, 328,728 ft. of intertrack space and 142,797 ft. of border. One foot of center ditch is charged as equal to two feet of border. The total is, therefore, 400,136 ft. of equated intertrack space in three weeks, Sundays excluded, a daily average of 22,230 ft. of equated inter-track space. The best day saw 32,903 feet cleaned. A 200-day working season (eight calendar months) at the average rate for this three weeks, would give an annual production of 4,446,000 ft. of center ditch, which is 105 miles monthly and 842 miles per year.

Including dirt handling equipment installed on purchaser's flat cars, the machine costs \$125,000. Operated on a contracting basis in 1933, the over-all cost per foot to the railroad company, including supervision, train crew wages, locomotive rental and expenses, insurance coverage for casualty, property and liability, complete disposal of all dirt, and all charges for ballast cleaning, was 4.17 cents for center ditch and 2.12 cents for border.

Under railroad ownership and operation there are possibilities for still lower costs by reduction of overhead through distribution over the output of a full working season, and elimination of some insurance charges.

If this ballast cleaner were self-propelled, costing \$175,000, it is estimated the cost per foot would be reduced 20 per cent, and output increased about 10 per cent.

The operating crew consists of a general foreman and two 8-hr. shifts of seven men each. There is a shift foreman; one operator each for the two cleaner boxes, towing winch, and dragline scraper; one laborer each for the ballast shapers at rear of the two cleaner boxes.

A portion of our former report on the subject "Plows used in conjunction with ballast discers" brought out little information. In answer to its questionnaire, the Committee received no information on plows used in conjunction with ballast discers. "There are plows and there are discers, but apparently they have not yet been brought into conjunction. Quite a number of discers are in service which were made by bolting discer attachments on to the sides of track motor cars. These are not very effective, but there are on the market heavy outfits to be operated at a slow speed with powerful special motor cars and they do excellent work in gravel ballast. A car is now being developed which will have a plow in conjunction with a discer and this arrangement will undercut the ends of the ties, throw the ballast out with the discs and permit the water to drain out. After a period of two or three weeks has elapsed, another trip will be made using the discs to throw the ballast back against the ends of the ties and reshape the border."

Since that time a continuous period of experimentation and development has produced a Ballast Drainage Car with scarifiers and bladers, adapted to work in stone ballasted shoulders.

Fig. 3 shows the machine in position for road movement, with all parts within the A.R.A. limits. Fig. 4 shows the machine in working positions, and Fig. 5 is a closeup of the scarifying wing.

On each side are two separate "wings", the front wing for scarifying, and the rear for blading. Either wing is ready for immediate use by simply connecting the cable of pneumatic hoist, and releasing safety chains.

FIG. 3.—Showing Ballast Agitator in Travel Position.  
(Arms Raised and Lowered by Air)

None of the wings need additional weight to hold them down while scarifying or blading; all are ruggedly built of heavy castings and structural steel electrically welded into solid units of adequate weight and strength.

Using scarifiers, the machine makes three to five trips, each time ploughing a deeper layer of ballast. The scarifier points loosen the pieces of rock from surrounding dirt, rolling and shoving the mixture outward against a stop plate. Being lined like the edge of a plowshare, the gangs of scarifiers wedge through opposite shoulders with minimum traction, 10 points cutting easily because a furrow is already open beside each.

This leaves ballast piled near the toe line for drying out a few days if muddy (and the crib is full and rail well anchored). Rains at this stage help to wash dirt out. When dry, the rock is bladed back in two trips, to approximate shoulder section. The first blading places the upper and cleaner ballast against the end of ties. The second cut slopes the outer and lower shoulder, which is further cleaned by rains.

It will be seen that much dirt is rubbed off and sifted down in the process of plowing ballast out, then blading it back. The drier the ballast, the better the cleaning. So far most effort has been toward getting the water out of a maximum mileage of track.

FIG. 4.—Showing Ballast Shaping Blades.

FIG. 5.—Indicating Location of Ballast Agitating Forks.

## REPORT OF COMMITTEE XII—RULES AND ORGANIZATION

### *To the American Railway Engineering Association:*

Your Committee respectfully presents herewith report covering the following subjects:

1. Revision of Manual, collaborating with appropriate committees (Appendix A).

The Committee offers for approval and printing in the Manual the changes outlined in Appendix A, the same to be substituted for the existing subject-matter.

2. Rules for the guidance of employees of the Maintenance of Way Department, with special reference to:

- (a) Maintenance of bridges, collaborating with Committees VIII—Masonry, and XV—Iron and Steel Structures (Appendix B).
- (b) Maintenance of telegraph and telephone lines and appurtenances, collaborating with committee appointed by Telegraph and Telephone Section (Appendix C).
- (c) Maintenance of terminal structures other than buildings, collaborating with Committees XIV—Yards and Terminals and XXIII—Shops and Locomotive Terminals.

2-a. The Committee offers for approval and printing in the Manual Rules 1150 to 1164 inclusive, as shown in Appendix B—Rules for Maintenance of Bridge—Masonry and composite structures. These rules have the approval of Committees VIII—Masonry and XV—Iron and Steel Structures.

2-b. The Committee offers as information in Appendix C rules for maintenance of telegraph and telephone lines and appurtenances. These rules have been prepared by a sub-committee of the T&T Section and are submitted as particularly applying to Maintenance of Way employees. The Committee requests that members of the Association who are interested in this phase of Maintenance of Way work, carefully go over these rules and submit to the Committee any criticism or suggestions.

- 2-c. The Committee has no further rules to offer on this subject.

3. The Committee submitted as information last year appropriate titles for Assistant Engineers, in all departments. This information was collected after considerable investigation and study and the membership was appealed to for criticisms and suggestions. Since the submission of this information no criticisms or suggestions have been received. The Committee, therefore, submits, in Appendix D, these titles for approval and printing in the Manual.

4. The Committee offered as information last year a number of rules on fire prevention as applying to the Maintenance of Way Department. These rules have been revised and rearranged to meet some criticisms received and they are now offered in Appendix E for approval and printing in the Manual. These rules have the approval of the National Board of Fire Underwriters and Railway Fire Protection Association.

Respectfully submitted,

THE COMMITTEE ON RULES AND ORGANIZATION,

E. H. BARNHART, *Chairman.*

## Appendix A

### (1) REVISION OF MANUAL

P. D. Coons, Chairman, Sub-Committee.

#### RULES FOR THE INSPECTION OF BRIDGES, TRESTLES AND CULVERTS

GENERAL (p. 847, 1929 Manual)

##### *Present Form*

1353. (1st sentence) These bridge inspectors shall forward to the..... in (duplicate) (triplicate) .....on the proper form provided, a report of each bridge, trestle or culvert inspected, enumerating in detail the parts of each structure inspected, giving the conditions found in each individual part.

##### *Proposed Form*

1353. (1st sentence) These bridge inspectors shall forward to the..... in (duplicate) (triplicate) .....on form 1110 Revised or 1110-A as appropriate, a report of each bridge, trestle or culvert inspected, enumerating in detail the parts of each structure inspected, giving the conditions found in each individual part.

FIELD INSPECTION (p. 853, 1929 Manual)

1359. (1st sentence) The Division Bridge Inspector shall each day, after a structure is inspected, send to the..... a report on approved form in (duplicate) (triplicate) showing defects, if any, giving a minute description of said defects.

1359. (1st sentence) The Division Bridge Inspector shall each day, after a structure is inspected, send to the..... a report on form 1110 Revised or 1110-A as appropriate in (duplicate) (triplicate) showing defects, if any, giving a minute description of said defects.

\* FORMS (p. 859, 1929 Manual).

##### \* Forms

1415. Form to be used by Division Bridge Inspector for general inspection of all bridges, trestles and culverts should be printed in books of 100 or more leaves, each leaf being perforated and having a carbonized back. The backs of the books should be stiff cardboard or linen and size should not exceed 4½ inches by 6½ inches.

##### \* Forms—Eliminate

1415. Eliminate

\* Forms not yet submitted

\* Eliminate.

## Appendix B

### (2-A) RULES FOR MAINTENANCE OF BRIDGES—MASONRY

A. B. Griggs, Chairman, Sub-Committee.

1150. Driftwood or other débris must not be permitted to accumulate around the base of bridge masonry.

1151. All obstructions to proper drainage in the channel must be removed. If obstructions are caused by a faulty channel, changing channel should be given consideration.

1152. Where scouring or undermining of bridge masonry is found, riprap or other forms of protection must be installed.

1153. Where foundations are badly undermined or otherwise endangered, protection shall be provided for the structure.

1154. Where examination reveals weakness of masonry from any cause, such conditions must be reported.

1155. Where arches or culverts are subjected to excessive scouring or undermining, protection must be provided.

1156. Where masonry is subjected to the action of ice or other abrasion causing disintegration, protection work of proper design must be installed.

1157. Where masonry is founded on timber, previously under water which subsequently becomes exposed to the air, proper foundation must be substituted.

1158. Where movement has become restricted at expansion joints, they must be repaired to allow the joints to function as designed.

1159. Where indication of failure of arch rings occurs as evidenced by cracks or flattening of the arch, temporary support must be provided until permanent repairs can be made.

1160. Drains or "weep holes" in bridge masonry must be kept open to insure full operation of the drainage system.

1161. Inadequate drainage of bridge masonry must be remedied.

1162. Bridge seats that have become weakened through deterioration or overload must be replaced.

1163. Areas of masonry that have become deteriorated must be repaired prior to reaching an extent endangering the strength of the structure.

1164. Joints in stone masonry must be kept well pointed. Before pointing, all loose material must be removed and the joints well-moistened.

### Appendix C

## (2-B) RULES FOR MAINTENANCE OF TELEGRAPH AND TELEPHONE LINES AND APPURTENANCES

W. C. Barrett, Chairman, Sub-Committee.

### General

A-1. The following rules covering outside communication plant are for the guidance of maintenance of way employees and are based upon specifications and instructions contained in the Manual of Recommended Practices of the Telegraph and Telephone Section. (For details concerning the construction and maintenance of outside communication plant, see Section 1 of the Manual.)

### Clearances

B-1. AERIAL LINES ALONG RAILROADS.—All poles shall be set so that the minimum horizontal clearance of any wire, guy or other attachment will be eight feet from the outer edge of the nearest main track rail. Under normal conditions with poles carrying ten-pin crossarms, this minimum clearance will be obtained by setting poles thirteen feet from the rail.

B-2. Where it is impracticable to obtain the clearance specified above, the poles may be set with a minimum horizontal clearance of eight feet from the outer edge of the nearest main track rail, but the lowest attachment in such cases shall be at least twenty-five feet above the rails. Where the poles have a horizontal clearance of from ten to thirteen feet inclusive, the lowest crossarm should be not less than twenty feet above the rails. The minimum vertical clearance for any crossarms should be ten feet above the ground.

B-3. Poles may be set at a minimum horizontal clearance of seven feet from the outer edge of the nearest track rail, providing the lowest attachment is at least twenty-five feet vertically above the rails. At loading sidings space shall be left for a driveway.

B-4. At private and farm crossings the clearance shall be such that the wires or other attachments will not interfere with the free use of such roads. Over driveways leading to private residences the minimum clearance shall be fifteen feet. At private or farm crossings used for the passage of wagons and farm machinery a clearance of over fifteen feet may be necessary. At crossings used only by cattle or pedestrians, the clearance may be reduced safely to ten feet.

B-5. When a cable attachment is made to a metal bridge, the cable and messenger shall be insulated from the bridge structure. The type of insulating attachment best suited for use in any particular situation will depend upon local conditions, but in most cases it will be sufficient to support the messenger on wood blocks, clamped or bolted to the bridge structure.

B-6. Trees should be trimmed so as to give at least a four-foot clearance from all wires. If the trees are not located on a railroad property permission shall be obtained from the owner before trimming. If permission cannot be obtained, the fact should be reported.

B-7. Care should be taken to avoid contact, either direct or by means of material or tools, with wires on communication pole lines designated by a stripe painted on the crossarm or by the use of a different form of insulator from the others on the pole line.

B-8. Telltale poles or other structures should not be erected so as to interfere with communication wires or so as to endanger men working on such structures by coming in contact with wires.

B-9. If poles or wires that are broken obstruct tracks, clear same immediately, exercising proper care in handling wires to avoid interruption to service on wires that are intact. If power wires are carried on the line, do not touch or come in contact with any wires except by the use of properly insulated tools.

B-10. Worthless junk, such as scraps of old iron wire, must be buried or otherwise satisfactorily disposed of. If left around, scraps of wire may be thrown in the line by persons passing by.

B-11. AERIAL CROSSINGS.—Poles or towers supporting the crossing span shall, unless physical conditions prevent, have side clearance of not less than twelve feet from the nearest track rail except that at sidings a clearance of not less than seven feet may be allowed. At loading sidings sufficient space shall be left for a driveway. Where necessary to provide safe operating conditions which require uninterrupted view along the tracks for signals, signs, etc., the parties concerned shall cooperate to provide greater clearances than those specified above.

B-12. Report all vertical clearances above rails that do not conform to:

(a) The clear headroom between the lowest wire, cable, guy or suspension strand and the top of rail shall be not less than twenty-seven feet, except where the wires or cables are paralleled in the same highway by a trolley contact conductor at a lower level, the clearance between such wires or cables and the top of rail may be reduced to twenty-five feet.

(b) Where the distance from the nearest crossing support to the farthest track rail exceeds seventy-five feet, the clearance specified above shall be increased by two-tenths of a foot for each ten feet in excess of seventy-five feet; provided, however, that the above distance from the nearest pole to the farthest track rail need not be considered more than one-half the span length.

B-13. Unless approved by the railroad company, attachments to railroad steel bridges shall not be made by devices that require the drilling or cutting of the bridge structure or the removal of rivets, and the attachments shall be made so that wires, cables and suspension strand will not be in metallic contact with the bridge structure.

B-14. The clearance of any conductor from the face of the abutment shall be not less than three feet for steel bridges.

B-15. Cables or twisted pair wires and their suspension wires may be attached directly to the face of the abutment if located not less than twenty-four inches below the elevation of the bridge seat, and they shall provide suitable clearances for pedestrians, vehicles, etc., as may be necessary.

B-16. The clearance between any conductor attached to the bridge in open construction, and any portion of the bridge structure shall preferably be not less than six inches, except where this is impracticable, the value may be reduced to not less than three inches.

B-17. The clearance between any conductor not attached to the bridge and any portion of the bridge structure shall preferably be not less than one foot, except where this is impracticable, the value may be reduced to not less than six inches.

## Underground Construction

C-1. The underground system shall be so located as to be subject to the least amount of disturbance. Care shall be exercised to avoid catchbasins, pipes, or underground structures which have been installed or are planned for the future.

C-2. The top of all conduit protection, except as hereafter specified, shall generally be located at a depth of not less than three feet six inches below the base of the rail. Where this is impracticable, or for other reasons, this clearance may be reduced by agreement between the parties concerned. In no case, however, shall the top of the conduit

protection extend higher than the bottom of the ballast section which is subject to working or cleaning.

C-3. Where unusual conditions exist or where proposed construction would interfere with existing construction a greater depth than specified above may be required.

C-4. Where physical and chemical conditions will permit, a conduit consisting of not more than two iron pipes, not exceeding three inches in diameter, or two creosoted wood ducts, not exceeding four and one-half inches square, used for telegraph, telephone or other communication lines, may be laid in the ground beneath railroad tracks without any form of protection at a minimum depth of eighteen inches below the base of the rail unless the worked ballast section of the roadbed exceeds eighteen inches, in which case the conduit shall be laid below the ballast section.

C-5. In no case shall the conduit structure be less than eighteen inches below the surface of the ground.

C-6. When underground conduit construction crossing tracks terminates on terminal poles immediately adjoining the tracks, or in manholes, handholes, etc., which project above the surface of the ground, the side clearance, unless physical conditions prevent, shall be not less than twelve feet from the nearest track rail, except that at sidings a clearance of seven feet may be allowed. At loading sidings sufficient space shall be left for a driveway. Manholes and handholes shall in no event be located closer than seven feet from the nearest rail.

C-7. Where the conduit system parallels the railroad right-of-way it is desirable to locate it as far as practicable from the railroad tracks. Where it is impracticable to locate the conduit system three feet or more horizontally from the nearest rail, special types of construction shall be used or special precautions taken.

C-8. Where necessary to prevent caving, the sides of trench shall be supported with suitable planks and bracing. No bracing shall extend above the base of the rail or be attached in any way to the rails or ties.

C-9. The trench shall be backfilled with earth to the subgrade line, using the better material next to the conduit structure. Stones shall not be placed next to the conduit structure. If any large stones that were removed are replaced, they shall be replaced in a vertical position. Excavation below the bottom line of the trench shall be backfilled with good earth and well tamped. Track ballast shall be replaced under railroad supervision.

C-10. All surplus material remaining after the work has been finished shall be removed, and if disposed of upon railroad property shall be placed under railroad supervision.

C-11. When excavating for any purpose, or working the ballast section of the roadbed, precautionary measures should be taken to avoid damage to underground communication facilities.

## General Rules

D-1. Report all cases of prospective foreign line construction which will cross over or under or paralleling their own lines and all unsafe conditions at existing wire crossings.

D-2. Bring to the attention of the properly designated official such matters as may come to their knowledge which in any way would be advantageous to the company's service or which might adversely affect the company.

D-3. Telephone dispatching and message circuits on communication pole lines are generally designated by the letter "D" for the dispatcher's circuit and the letter "M" for the message circuit marked on the crossarm between the two wires of each circuit. Where circuits are so designated, users of portable telephones should be instructed to make connections with the dispatcher's or message telephone circuits only at points where circuits are so designated.

D-4. Water must not be used to extinguish electrical flames. Sand, dry earth, or fire extinguishers approved for electrical fires should be used. A stream of water must not be played on a "live" third rail or electric wire.

D-5. Employees shall not climb into wires when not aware of their operating voltages. They must be able to identify supply circuits which are sometimes located on the lower crossarms.

D-6. If wires hang low over any track, street or thoroughfare, leave sufficient men to guard them, until raised to proper clearance.

D-7. Be on the alert to detect trespassers who may be shooting or stoning cables, wires, insulators, etc. Take necessary action to prevent damage to plant and make proper report of details to properly designated official for further handling.

D-8. The removal of dry grass and inflammable debris or refuse from around poles will reduce the fire hazard. In burning refuse material, select a location where the communication lines or other property will not be damaged.

D-9. The carrying of blow torches, open flames, lighted cigars, cigarettes or pipes into or near the openings of manholes is strictly prohibited.

D-10. Spreaders, ditchers and other roadway machinery must be operated so as not to interfere with the communication plant.

D-11. As grass and forest fires may seriously damage the communication plant, it is essential that every effort be made to prevent them and to cooperate fully with National and State forestry fire prevention measures.

D-12. Wire connections to water or other pipes, ground rods, etc., should not be loosened or removed, and where such conditions are found they should be reported at once to proper authority. The function of such wires is to provide return paths for various currents transmitted over the lines and in connection with electrical protection to provide drainage for currents resulting from crosses with foreign circuits or from lightning. This removal or loosening of these connections may mean serious injury to employees using telephone or working telegraph wire at that location, in case of crosses with foreign circuits or from lightning discharges.

D-13. Prompt report should be made to the properly designated official of the following conditions whenever noted:

Poles that are badly rotted, burned, split or otherwise considered unsafe.

Poles that are leaning.

Poles that have been washed out.

Dead trees, branches or vines overhanging or leaning toward the lines.

Fires which occur in close proximity to the line.

Any wire or rubbish that may be hanging on the wires.

Broken or decayed crossarms.

Pins that may be broken or pulled out of crossarms.

In case of a general line prostration such as a storm break, report nature, location and extent of damage.

In the case of foreign supply line crossing failures obstructing the tracks of the railroads, no attempt shall be made to remove the high voltage wires until it is definitely known that the current is shut off. When this has been ascertained, such wires shall be removed from obstructing the track and the owner notified.

Manholes where gas is detected escaping from it.

Cables that are hanging loose from messenger wires as a result of cable rings or other supports failing.

## Appendix D

### (3) APPROPRIATE TITLES FOR ASSISTANT ENGINEERS

Richard Brooke, Chairman, Sub-Committee.

|     | <i>Duties of Position</i>                                                                    | <i>Reporting to</i>                        | <i>Proposed Title</i>       |
|-----|----------------------------------------------------------------------------------------------|--------------------------------------------|-----------------------------|
| (1) | In charge of office engineering work in office of Chief Engineer                             | Chief Engineer or Assistant Chief Engineer | Office Engineer             |
| (2) | Special investigations, studies, estimates and reports                                       | Chief Engineer or Assistant Chief Engineer | Special Engineer            |
| (3) | In charge of reconnaissance and of location on an entire system, or region of a large system | Chief Engineer                             | Locating Engineer           |
| (4) | In charge of a reconnaissance or location on a specific project                              | Locating Engineer                          | Assistant Locating Engineer |

| <i>Duties of Position</i>                                                                      | <i>Reporting to</i>                                                   | <i>Proposed Title</i>                      |
|------------------------------------------------------------------------------------------------|-----------------------------------------------------------------------|--------------------------------------------|
| (5) In charge of construction on an entire system, or region of a large system                 | Chief Engineer                                                        | Construction Engineer                      |
| (6) In charge of large construction projects                                                   | Construction Engineer                                                 | Assistant Construction Engineer            |
| (7) In charge of a specific project, such as ten miles of new line or equivalent               | Construction Engineer or Assistant Constr. Engineer                   | Resident Engineer                          |
| (8) General inspection of construction work                                                    | Construction Engineer                                                 | Construction Inspector                     |
| (9) In charge of office engineering work in office of Construction Engineer                    | Construction Engineer                                                 | Office Engineer, Construction              |
| (10) Special maintenance investigations                                                        | Chief Maintenance Officer                                             | Special Engineer, Maintenance              |
| (11) * Preparation of plans and estimates and supervision of field and office engineering work | Division Engineer                                                     | Assistant Engineer, Maintenance            |
| (12) Inspection of track and road-bed                                                          | Chief Maintenance Officer or an Assistant                             | Maintenance Inspector                      |
| (13) Inspection of bridges and/or buildings on an entire system, or region of a large system   | Chief Maintenance Officer or Bridge Engineer and/or Building Engineer | General Bridge and/or Building Inspector   |
| (14) Special bridge and/or building investigations, studies, estimates and reports             | Chief Maintenance Officer or Bridge Engineer and/or Building Engineer | Special Engineer, Bridges and/or Buildings |
| (15) Bridge design (particular projects)                                                       | Bridge Engineer or an Assistant                                       | Bridge Designer                            |
| (16) Bridge erection on a specific project                                                     | Bridge Engineer                                                       | Assistant Engineer, Bridge Erection        |
| (17) Building design and erection                                                              | Building Engineer                                                     | Assistant Engineer, Buildings              |
| (18) Water service, design, construction and/or maintenance                                    | Chief Water Service Officer                                           | Assistant Engineer, Water Service          |
| (19) Miscellaneous valuation work                                                              | Valuation Engineer                                                    | Assistant Engineer, Valuation              |

\* This title was adopted by the Convention in March, 1931, and printed in Bulletin 347, page 29 (Revisions and Additions to the Manual).

## Appendix E

### (4) RULES FOR FIRE PREVENTION AS APPLYING TO MAINTENANCE OF WAY DEPARTMENT

H. C. Hayes, Chairman, Sub-Committee.

#### General

33. Employees must give full co-operation to fire prevention measures and be familiar with location and use of nearest fire alarms.

#### Division Engineers

302. They must see that employees under their jurisdiction are properly instructed in fire prevention rules, alert in decreasing fire hazards and exacting in the maintenance and operation of fire fighting apparatus. When locating buildings and structures, they will see that attention is given fire prevention.

### Supervisors of Track

316. They must give particular attention to fire hazards from adjoining property and from structures erected on railway property by lessees.

317. They must see that those under their supervision do not obstruct fire roads, fire hydrants and hose houses.

318. They must see that no lumber, ties, piling or other inflammable materials are piled in close proximity to any important building and that automobiles or trucks are not parked in a manner which constitutes a fire hazard.

319. They must know that their foremen understand and observe fire prevention rules.

### Supervisors of Bridges and Buildings

374. They must give particular attention to fire hazards where the risk is extreme, such as oil houses, paint shops, wood coal chutes, and cotton platforms.

375. They must make proper reports to superiors of any unguarded fire hazards.

376. They must see that those under their supervision do not obstruct fire escapes and exit passages thereto, fire doors, hose reels, fire hydrants, fire roads, and hose houses.

377. They must see that all sprinkler systems and fire fighting apparatus under their jurisdiction are maintained in accordance with the National Fire Underwriters Code.

378. They must arrange through their superior officers for the proper cooperation of all municipal fire departments.

379. They must make recommendations for fire stops when necessary, and for the removal of any fire hazards.

379-A. They must see that inflammable materials are stored so as to confine any fire to the place of origin.

379-B. They must know that their foremen understand and observe fire prevention rules.

### Supervisors of Water Service

423. They must know that fire pumps and fire lines under their jurisdiction are in proper working condition, and that fire hydrants and hose are always ready for instant use.

424. They must call attention to points where connections might be made to municipal fire mains.

425. They must know that their foremen understand and observe fire prevention rules.

## REPORT OF COMMITTEE VI—BUILDINGS

|                                 |                 |                            |

| J. N. GRIM,                     | A. H. MORRILL,  | C. L. WENKENBACH,          |
|                                 |                 | <i>Committee.</i>          |

*To the American Railway Engineering Association:*

Your Committee respectfully presents herewith report covering the following subjects:

- (1) Revision of Manual (Appendix A).
- (2) Preparation of Specifications for Railway Buildings (Appendix B).
- (3) Remodeling Freight Houses for Accommodation of Truck Door-to-Door Delivery of Freight (Appendix C).
- (4) Bus Terminal Buildings, Isolated and in Conjunction with Railway Stations, collaborating with Committee XIV—Yards and Terminals (Appendix D).
- (5) Application of stainless and rust-resisting metals to building construction (Appendix E).
- (6) Vermin and rat-proofing in buildings (Appendix F).
- (7) Relative merits of wood and fireproof roof structures, which should include wood, hollow tile fireproofing, concrete and cement tile, etc. (Appendix G).
- (8) Causes of dust explosions in grain elevators and methods of obviating the hazard (Appendix H).
- (9) Mill type and other heavy wood construction for railway buildings (Appendix I).
- (10) Study the economic value of various basic and composite materials used in building construction and maintenance (Appendix J).

### Action Recommended

1. That the changes in the Manual as recommended in Appendix A be approved and the revised text be substituted for that now appearing in the Manual.

2 a.—That the specification for Electrically Operated Freight or Baggage Elevators, previously published in the Proceedings as part of Appendix A, section 29, pages 682 to 688, both inclusive, of Bulletin 354, Vol. 34, Proceedings 1933, be printed in the Manual.

b.—That the specifications submitted with this report as Appendix B be published in the Proceedings as information and for criticism.

c.—That this subject be reassigned.

(3) That the report in Appendix C be received as information and as a final report and the subject discontinued.

(4) That the subject be reassigned as recommended in Appendix D.

(5) That the subject be reassigned as recommended in Appendix E.

- (6) That the subject be reassigned as recommended in Appendix F.
- (7) That the report in Appendix G on Relative Merits of Wood and Fireproof Roof Structures be received as information.
- (8) That the report in Appendix H on Causes of Dust Explosions in Grain Elevators be received as information.
- (9) That the subject be reassigned as recommended in Appendix I.
- (10) That the subject be reassigned as recommended in Appendix J.

Respectfully submitted,

THE COMMITTEE ON BUILDINGS,

G. A. RODMAN, *Chairman.*

## Appendix A

### (1) REVISION OF MANUAL

G. A. Belden, Chairman, Sub-Committee; A. C. Copland, F. R. Judd, A. L. Sparks, O. G. Wilbur, E. K. Mentzer.

Your Committee recommends the adoption of the following revisions in the subject-matter now appearing in the Manual:

#### 1. Page 316. Section 10-A, Concrete Roofing Tile

First paragraph at top of page reads as follows:

"The joints of large flat tile shall be pointed where necessary so as to provide a smooth surface for the application of the composition roofing, which is to be applied with a high melting point adhesive."

Revision recommended:

"The joints of large flat tile shall be pointed where necessary so as to provide a smooth surface for the application of the roofing."

#### 2. Pages 319 to 327—Section 10-D, Built-up Roofing

Substitute the following revised specifications, dated July 26, 1933, for the specifications now published on these pages:

### REVISED SPECIFICATIONS FOR BUILT-UP ROOFING

#### Section 10-D

#### BUILT-UP ROOFING

##### MATERIALS

#### 1. General

The contractor shall furnish all labor, material, tools and equipment necessary to entirely complete the roofing to make the work watertight, and shall leave it in a neat and finished condition.

#### 2. Materials

**PITCH.**—Pitch shall be the best quality, straight-run American coal-tar pitch, distilled direct from coal-tar and free from water and ammonia. It shall contain not less than 15 per cent nor more than 36 per cent of free carbon. The melting point shall be not below 140 degrees Fahr. nor above 150 degrees Fahr. (A.S.T.M. cube method) and it shall show a flashpoint of not less than 240 degrees Fahr.

**ASPHALT.**—Asphalt shall be a combination of natural asphalt prepared and combined properly in which inherent mineral matter will be permitted but to which no mineral matter shall be added.

For roofs having a slope not greater than 3 inches per foot the melting point shall be between 140 and 165 degrees Fahr. and for roofs having a slope greater than 3 inches per foot, the melting point shall be between 165 and 180 degrees Fahr., as determined by the "Standard method of test for softening point of bituminous materials other than tar products" (ring and ball method) in accordance with the standard methods of the A.S.T.M.

The penetration at 77 degrees Fahr. under a load of 100 grams for 5 seconds shall be not less than 20 nor more than 30. The ductility at 77 degrees Fahr., when a briquette of the material having a minimum cross-section of 1 square centimeter is pulled apart at the rate of 5 centimeters per minute, shall be not less than 10 centimeters for asphalt having a melting point under 165 degrees Fahr., nor less than 3 centimeters for asphalt having a melting point between 165 degrees Fahr. and 180 degrees Fahr. The loss of a 50 gram sample at 325 degrees Fahr. for 5 hours shall not exceed 1 per cent. The penetration of the residue at 77 degrees Fahr. under a load of 100 grams for 5 seconds shall be not less than 10 nor more than 15. The methods of making tests shall be in accordance with the standard of the A.S.T.M., and penetrations are in hundredths of a centimeter.

**ASPHALT PRIMER.**—Asphalt primer for concrete and gypsum decks shall weigh not less than 7 lb. per gallon and shall be made from asphalt, of the quality specified under "Asphalt" fluxed to the proper consistency. The melting point of the asphalt primer shall be such as will permit the subsequent application of hot asphalt to amalgamate immediately with it.

**ROOFING FELTS.**—All felts shall be either 32 or 36 inches wide. They shall be of the kind and weight hereinafter specified. They shall have sufficient pliability to meet the requirements of application. Samples taken from the felts weighing approximately 14 lb. per 108 sq. ft. shall bend flat through 180 degrees without cracking and samples from the felts weighing approximately 60 lb. per 108 sq. ft. shall bend around one-half inch radius through 180 degrees without cracking. A variation of seven (7) per cent from the weights of the felts specified will be allowed. The impregnating compounds shall be of the qualities specified and shall be of the proper consistency for saturating the felts.

**MANUFACTURED ROOFING.**—Manufactured roofing material shall be delivered at the site in the original sealed packages of the manufacturer, and each package shall be wrapped and labeled properly in order that it may be identified easily.

**FLASHING.**—Where flashings, gravel stops and eave trim are to be of metal, they shall be in accordance with the provisions of Section 11, Sheet Metal Work; otherwise they shall be as hereinafter specified.

**GRAVEL AND SLAG.**—Gravel shall be hard, durable, free from clay, loam, and other foreign substances, and shall range from  $\frac{1}{4}$  to  $\frac{5}{8}$  inch.

Slag shall be granulated furnace slag, free from sand, dirt and other foreign substances, and shall range from  $\frac{1}{4}$  to  $\frac{5}{8}$  inch.

### 3. Application

The roof decks shall be clean, smooth, thoroughly dry and free from projections which would injure the roof coverings. All roofing shall be laid smoothly, without wrinkles or buckles, and finished surfaces shall be free from cracks and bubbles.

Before applying the roofing over wood decks, all loose knots and other flaws shall be removed and knot holes and large cracks shall then be covered with tin or other sheet metal nailed in place.

For gypsum or concrete decks, the joints and surfaces shall be made tight and flush, and all loose and uneven surfaces shall be leveled up before the roofing is applied.

## TYPE A-1

**Tarred Rag Felt, Pitch and Gravel (or Slag) Over Wood or Pre-Cast Units**

1. This type of roofing shall be limited to use on wood or pre-cast gypsum roofs having a slope not greater than 2 inches per foot and on pre-cast concrete roofs having a slope not greater than 1 inch per foot.

2. This type of roofing shall be composed of five layers of not less than 14 lb. tarred rag felt, a minimum of 150 lb. of pitch per 100 sq. ft. and coated with gravel or slag.

3. If on wood, lay one thickness of rosin-sized building paper or unsaturated felt weighing not less than 5 lb. per 108 sq. ft., lapping the sheets at least one inch; if on pre-cast units this shall be omitted.

4. Over the entire surface lay two layers of tarred felt, weighing not less than 14 lb. per 108 sq. ft. per layer, lapping each sheet of each layer 17 inches over the preceding sheet for 32-inch wide felt or 19 inches for 36-inch wide felt, end laps not less than 4 inches. Sheets shall be nailed as often as necessary to hold them in place until the remaining felt is laid. These layers shall be turned up against vertical surfaces not less than 6 inches and securely fastened.

5. Over the two layers of 14 lb. felt apply metal eave strips and gravel stops at all edges of the roof, as specified in paragraph 6, Section 11, Sheet Metal Work.

6. Coat the entire roof surface uniformly with hot pitch, using not less than 25 lb. per 100 sq. ft.

7. Over the entire surface lay three layers of tarred felt, lapping each sheet of each layer 22 inches over the preceding sheet for 32-inch wide felt or 25 inches for 36-inch wide felt, with end laps not less than 6 inches. Hot pitch shall be mopped the full 22 inches or 25 inches respectively on each sheet so that in no place shall felt touch felt, using not less than 25 lb. of pitch per 100 sq. ft. between successive layers. Any nailing necessary shall be done in such a manner that all nails will be covered by not less than two layers of felt. Nails shall be galvanized and shall be driven through tin or zinc caps. These layers shall be cut off at vertical surfaces and thoroughly mopped along the edges.

8. Flashings shall be installed at all intersections of the roof with vertical surfaces, and the plans will show whether sheet metal or felt flashings are to be used.

Where metal flashings are called for they shall be furnished and installed in accordance with paragraph 4, Section 11, Sheet Metal Work and, in addition, the felt and pitch reinforcement shall be installed as follows:

After all plies of roofing have been laid and before application of the slag or gravel surface, the contractor shall set in separately at the angle of the roof deck and vertical surface 3 plies of 14 lb. tarred felt, cemented together with coal-tar pitch. These plies shall extend out on the roof at least 4 inches and up the vertical surface 6 inches. The last ply shall be coated with coal-tar pitch and then the metal base and counter flashing installed as specified in Section 11. The flange of the base flashing on the roof shall be coated with hot pitch into which shall be bedded a 4-inch strip of felt centered over the nailing course. This strip shall be coated with hot pitch into which shall be bedded a second strip of felt 6 inches wide and completely covering the first.

Where felt flashings are called for they shall consist of 3 layers of 14 lb. asphalt felt and a cap flashing of 85-lb. slate surfaced roll roofing. The felt strip shall be cemented to the roof and vertical surface and to each other with an approved plastic roofing cement, reinforced with mineral fiber.

The first strip of felt shall extend 6 inches up the vertical surface and 4 inches out on the roof, the second 8 inches up the wall and 5 inches on the roof and the third 10 inches up the wall and 6 inches out on the roof. Felt strips shall not exceed 10 ft. in length and shall be lapped at least 1 inch at all joints and joints broken. The cap flashing of mineral surfaced roofing shall extend at least 4 inches in masonry walls and down to the roof deck and shall be cemented to the base flashings with plastic roofing cement.

9. Coat the entire roof surface with hot pitch poured from a dipper, using not less than 75 lb. of pitch per 100 sq. ft. and into this while hot embed not less than 400 lb. of dry gravel (or 300 lb. of dry slag) per 100 sq. ft. In cold weather the gravel or slag shall be heated before being applied.

## TYPE A-2

**Tarred Rag Felt, Pitch and Gravel (or Slag) Over Homogeneous Roofs Cast in Place**

1. This type of roofing shall be limited to use on roofs having a slope not greater than 2 inches per foot.

2. This type of roof shall be composed of 5 layers of not less than 14 lb. tarred rag felt, a minimum of 215 lb. of pitch per 100 sq. ft. and coated with gravel or slag.

3. The entire roof surface shall be coated uniformly with hot pitch, using not less than 40 lb. per 100 sq. ft.

4. Over this lay two layers of tarred rag felt, weighing not less than 14 lb. per 108 sq. ft. per layer, lapping each sheet of each layer 17 inches over the preceding sheet for 32-inch wide felt or 19 inches for 36-inch wide felt, end laps not less than 4 inches. Hot pitch shall be mopped the full 17 inches or 19 inches respectively on each sheet, so that in no place will felt touch felt, using not less than 25 lb. of pitch per 100 sq. ft. between successive layers. These layers shall be turned up against vertical surfaces not less than 6 inches and securely fastened.

5. Over the two layers of 14 lb. felt apply metal eave strips and gravel stops at all edges of the roof as specified in paragraph 6, Section 11, Sheet Metal Work.

6. Coat the entire surface uniformly with hot pitch, using not less than 25 lb. per 100 sq. ft.

7. Over the entire surface lay three layers of tarred rag felt, lapping each sheet of each layer 22 inches over the preceding sheet for 32-inch wide felt or 25 inches for 36-inch wide felt, end laps not less than 6 inches. Hot pitch shall be mopped the full 22 inches or 25 inches respectively on each sheet, using not less than 25 lb. of pitch per 100 sq. ft. between succeeding layers. These layers shall be cut off at vertical surfaces. If roof decks are of gypsum, in addition to the above, the upper edge of each course of the third layer of felt shall be nailed to the roof deck with galvanized nails driven through tin or zinc caps.

8. Flashings shall be installed at all intersections of the roof with vertical surfaces and the plans will show whether sheet metal or felt flashings shall be used.

Where metal flashings are called for they shall be furnished and installed in accordance with paragraph 4, Section 11, Sheet Metal Work and, in addition, the felt and pitch reinforcement shall be installed as follows:

After all plies of roofing have been laid and before application of the slag or gravel surface, the contractor shall set in separately at the angle of the roof deck and the vertical surface, 3 plies of 14 lb. tarred felt, cemented together with coal-tar pitch. These plies shall extend out on the roof deck at least 4 inches and up the vertical surface 6 inches. The last ply shall be coated with coal-tar pitch and then the metal base and counter flashings installed as specified in Section 11. The flange of the base flashing on the roof shall be coated with hot pitch into which shall be bedded a 4-inch strip of felt centered over the nailing course. This strip shall be coated with hot pitch into which shall be bedded a second strip of felt 6 inches wide completely covering the first.

Where felt flashings are called for, they shall consist of 3 layers of 14 lb. asphalt felt and a cap flashing of 85-lb. slate surfaced roll roofing.

The felt strips shall be cemented to the roof and vertical surfaces and to each other with an approved roofing cement reinforced with mineral fiber. The first strip of felt shall extend 6 inches up the vertical surface and 4 inches out on the roof, the second 8 inches up the wall and 5 inches out on the roof, and the third 10 inches up the wall and 6 inches out on the roof. Felt strips shall not exceed 10 ft. in length and shall be lapped at least one inch at all joints and the joints broken. The cap flashing of mineral surfaced roofing shall extend at least 4 inches in masonry walls and down to the roof deck and shall be cemented to the base flashing with plastic roofing cement.

9. Coat the entire roof surface with hot pitch poured from a dipper, using not less than 75 lb. of pitch per 100 sq. ft. and into this, while hot, embed not less than 400 lb. of dry gravel (or 300 lb. of dry slag). In cold weather the gravel or slag shall be heated before being applied.

## TYPE B-1

**Asphalt Rag Felt, Asphalt and Gravel (or Slag) Over Wood or Pre-Cast Units**

1. This type of roofing shall be limited to use on wood or pre-cast gypsum roofs having a slope not greater than 4 inches per foot and on pre-cast concrete roofs having a slope not greater than 2 inches per foot.

2. This type of roofing shall be composed of 5 layers of not less than 14 lb. asphalt saturated rag felt, a minimum of 150 lb. of asphalt per 100 sq. ft. and coated with gravel or slag.

3. If on wood, lay one thickness of rosin-sized building paper or impregnated felt weighing not less than 5 lb. per 108 sq. ft., lapping the sheets at least one inch; if on pre-cast units this shall be omitted.

4. Over the entire surface lay two layers of asphalt saturated rag felt, weighing not less than 14 lb. per 108 sq. ft. per layer, lapping each sheet of each layer 17 inches over the preceding sheet for 32-inch wide felt or 19 inches for 36-inch wide felt, end laps not less than 4 inches. Sheets shall be nailed as often as necessary to hold them in place until the remaining felt is laid. These layers shall be turned up against vertical surfaces not less than 6 inches and securely fastened.

5. Over the two layers of 14 lb. felt apply metal eave strips and gravel stops at all edges of the roof as specified in paragraph 6, Section 11, Sheet Metal Work.

6. Coat the entire surface uniformly with hot asphalt, using not less than 25 lb. per 100 sq. ft.

7. Over the entire surface lay three layers of asphalt saturated rag felt, lapping each sheet of each layer 22 inches over the preceding sheet for 32-inch wide felt or 25 inches for 36-inch wide felt, end laps not less than 6 inches. Hot asphalt shall be mopped the full 22 inches, or 25 inches respectively on each sheet, so that in no place will felt touch felt, using not less than 25 lb. of asphalt per 100 sq. ft. between successive layers.

Any nailing necessary shall be done in such manner that all nails will be covered by not less than two layers of felt. Nails shall be galvanized and shall be driven through tin or zinc caps. These layers shall be cut off at vertical surfaces.

8. Flashings shall be installed at all intersections of the roof with vertical surfaces and the plans shall show whether sheet metal or felt flashings shall be used.

Where metal flashings are called for they shall be furnished and installed in accordance with paragraph 4, Section 11, Sheet Metal Work and, in addition, the felt and asphalt reinforcement shall be installed as follows:

After all plies of roofing have been laid and before application of the slag or gravel surface, the contractor shall set in separately at the angle of the roof deck and the vertical surface, 3 plies of 14 lb. asphalt felt, cemented together with hot asphalt. These plies shall extend out on the roof deck at least 4 inches and up the vertical surface 6 inches. The last ply shall be coated with hot asphalt and then the metal base and counter flashings installed as specified in Section 11. The flange of the base flashing on the roof shall be coated with hot asphalt into which shall be bedded a 4-inch strip of asphalt felt centered over the nailing course. This strip shall be coated with hot asphalt into which shall be bedded a second strip of felt 6 inches wide completely covering the first.

Where felt flashings are called for, they shall consist of 3 layers of 14-lb. asphalt felt and a cap flashing of 85-lb. slate surfaced roll roofing.

The felt strips shall be cemented to the roof and vertical surfaces and to each other with an approved plastic roofing cement reinforced with mineral fiber. The first strip of felt shall extend 6 inches up the vertical surface and 4 inches out on the roof, the second 8 inches up the wall and 8 inches out on the roof, and the third 10 inches up the wall and 6 inches out on the roof. Felt strips shall not exceed 10 ft. in length and shall be lapped at least one inch at all joints and the joints broken. The cap flashing of mineral surfaced roofing shall extend at least 4 inches in masonry walls and down to the roof deck and shall be cemented to the base flashing with plastic roofing cement.

9. Coat the entire roof surface with hot asphalt poured from a dipper, using not less than 75 lb. per 100 sq. ft. into which, while hot, embed not less than 400 lb. of dry gravel (or 300 lb. of dry slag). In cold weather the gravel or slag shall be heated before being applied.

**TYPE B-2****Asphalt Rag Felt, Asphalt and Gravel (or Slag) Over Homogeneous Roofs Cast in Place**

1. This type of roofing shall be limited to use on roof decks having a slope not greater than 4 inches per foot.

2. This type of roofing shall be composed of one coat of asphalt primer, five layers of not less than 14 lb. asphalt saturated rag felt, a minimum of 205 lb. of asphalt per 100 sq. ft., and coated with gravel or slag.

3. The entire surface, if of concrete, shall be coated uniformly with asphalt primer, using not less than 10 lb. per 100 sq. ft. and allowed to dry.

(If of gypsum, the surface shall be given two such coats.) Upon this there shall be applied a uniform coat of hot asphalt, using not less than 30 lb. per 100 sq. ft.

4. Over this lay two layers of asphalt saturated rag felt, weighing not less than 14 lb. per 108 sq. ft. per layer, lapping each sheet of each layer 17 inches over the preceding sheet for 32-inch wide felt or 19 inches for 36-inch wide felt, end laps not less than 4 inches and securely fastened. Hot asphalt shall be mopped the full 17 inches or 19 inches respectively on each sheet so that in no place will felt touch felt, using not less than 25 lb. of asphalt per 100 sq. ft. between successive layers. These layers shall be turned up against vertical surfaces not less than 6 inches and securely fastened.

5. Over the two layers of 14 lb. felt apply metal eave strips and gravel stops at all edges of the roof as specified in paragraph 6, Section 11, Sheet Metal Work.

6. Coat the entire surface uniformly with hot asphalt, using not less than 25 lb. of asphalt per 100 sq. ft. of roof surface.

7. Over the entire surface lay three layers of asphalt saturated rag felt, lapping each sheet of each layer 22 inches over the preceding sheet for 32-inch wide felt or 25 inches for 36-inch wide felt, end laps not less than 6 inches. Hot asphalt shall be mopped the full 22 inches or 25 inches respectively on each sheet, so that in no place will felt touch felt, using not less than 25 lb. of asphalt per 100 sq. ft. between successive layers. These layers shall be cut off at vertical surfaces.

If roof decks are of gypsum, in addition to the above, the upper edge of each course of the third layer of felt shall be nailed to the roof deck with galvanized nails driven through tin or zinc caps.

8. Flashings shall be installed at all intersections of the roof with vertical surfaces and the plans will show whether sheet metal or felt flashings shall be used.

Where metal flashings are called for they shall be furnished and installed in accordance with paragraph 4, Section 11, Sheet Metal Work and, in addition, the felt and pitch reinforcement shall be installed as follows:

After all plies of roofing have been laid and before application of the slag or gravel surface, the contractor shall set in separately at the angle of the roof deck and the vertical surface, 3 plies of 14-lb. asphalt felt, cemented together with hot asphalt. These plies shall extend out on the roof deck at least 4 inches and up the vertical surface 6 inches. The last ply shall be coated with hot asphalt and then the metal base and counter flashings installed as specified in Section 11. The flange of the base flashing on the roof shall be coated with hot asphalt into which shall be bedded a 4-inch strip of felt centered over the nailing course. This strip shall be coated with hot asphalt into which shall be bedded a second strip of felt 6 inches wide completely covering the first.

Where felt flashings are called for, they shall consist of 3 layers of 14-lb. asphalt felt and a cap flashing of 35-lb. slate surfaced roll roofing.

The felt strips shall be cemented to the roof and vertical surfaces and to each other with an approved plastic roofing cement reinforced with mineral fiber. The first strip of felt shall extend 6 inches up the vertical surface and 4 inches out on the roof, the second 8 inches up the wall and 5 inches out on the roof, and the third 10 inches up the wall and 6 inches out on the roof. Felt strips shall not exceed 10 ft. in length and shall be lapped at least one inch at all joints and the joints broken. The cap flashing of mineral surfaced roofing shall extend at least 4 inches in masonry walls and down to the roof deck and shall be cemented to the base flashing with plastic roofing cement.

9. Coat the entire surface uniformly with hot asphalt poured from a dipper, using not less than 75 lb. of asphalt per 100 sq. ft. into which, while hot, embed not less than 400 lb. of dry gravel (or 300 lb. of dry slag). In cold weather the gravel or slag shall be heated before being applied.

## TYPE C-1 (CLASS 2)

**Asphalt Impregnated Asbestos Felt and Asphalt (Smooth Surface) Over Wood or Pre-Cast Units**

1. This type of roofing shall be limited to use on roof decks having a slope not greater than 6 inches per foot for wood or pre-cast gypsum, and to slopes not greater than 3 inches per foot for pre-cast concrete, unless provision is made in the pre-cast concrete units for nailing.

2. This type of roofing shall be composed of one layer approximately 60 lb. and two layers not less than 14 lb. asphalt impregnated asbestos felt and a minimum of 85 lb. of asphalt per 100 sq. ft.

3. Lay sheets of asphalt impregnated asbestos felt weighing approximately 60 lb. per 108 sq. ft. directly over the sheathing. Lap the joints 2 inches and seal them with asphalt. Nail these sheets along the lap with barbed nails driven through tin caps, spaced 6 inches apart, and in parallel lines approximately 10 inches apart and approximately 10 inches from the laps, these nails to be spaced 18 inches apart and staggered. This 60-lb. felt shall be laid parallel to pitch of roof and turned up 6 inches above the roof deck at all vertical surfaces, but not cemented to vertical surfaces.

4. Over the 60-lb. felt apply metal eave strips at all edges of the roof as specified in paragraph 6, Section 11, Sheet Metal Work.

5. Mop the entire surface of the 60-lb. felt with asphalt, heated to flow freely, and, while hot, embed in it sheets of asphalt impregnated asbestos felt, weighing not less than 14 lb. per 108 sq. ft. in two-ply construction; this 14-lb. felt to be run at right angles to the 60-lb. felt, lapped 17 inches for 32-inch wide felt and 19 inches for 36-inch wide felt and turned up 6 inches above the roof deck at all vertical surfaces.

Mop the entire surface between plies with asphalt, heated to flow freely, and roll the felts closely behind the mop so that no missing of asphalt can possibly take place. Approximately 30 lb. of asphalt shall be used per 100 sq. ft. for each mopping between successive layers.

Nail the upper edge of each sheet with barbed nails driven through tin caps, spaced 9 inches apart; the center line of nail heads to be approximately  $\frac{3}{4}$ -inch below the upper edge of sheet.

6. Flashings shall be installed at all intersections of the roof with vertical surfaces and the plans will show whether sheet metal or felt flashings shall be used.

Where sheet metal flashings are called for they shall be furnished and installed in accordance with paragraph 4, Section 11, Sheet Metal Work, and shall consist of a metal base and counter flashing installed after the application of the last two plies of felt, but before the final coating of asphalt is applied. The flange of the base flashing on the roof deck shall be coated with asphalt into which shall be bedded a 4-inch strip of 14-lb. asbestos felt centered over the nailing course. This strip shall be coated with hot asphalt into which shall be bedded a second strip of felt 6 inches wide completely covering the first.

Where felt flashings are called for they shall consist of a base flashing of an approved special asbestos flashing material cemented to the vertical surface and the roof deck with hot asphalt, and a cap flashing of the same material turned into masonry walls not less than 4 inches and extending down to the roof deck, cemented to the base flashing, and coated with an approved elastic roofing cement, reinforced with mineral fiber. The base flashing shall extend 4 inches out on the roof deck and not less than 8 inches up the vertical surface and the upper edge shall be nailed to the vertical surface where nailing is possible. Brick or concrete walls shall be coated with asphalt primer before the flashing is installed. The edge of the base flashing on the roof shall be covered with a 4-inch strip of 14-lb. asbestos felt embedded in and coated with hot asphalt. End laps of base and cap flashing shall be 3 inches, with joints broken.

7. When the roof is otherwise complete, cover the entire surface with a mopping of hot asphalt, using not less than 25 lb. of asphalt per 100 sq. ft. of roof surface.

## TYPE C-1 (CLASS 3)

**Asphalt Saturated Rag Felt, Asphalt Impregnated Asbestos Felt and Asphalt (Smooth Surface) Over Wood or Pre-Cast Units**

1. This type of roofing shall be limited to roof decks having a slope not greater than 6 inches per foot for wood or pre-cast gypsum, and to slopes not greater than 3 inches per foot for pre-cast concrete, unless provision is made in the concrete for nailing.

2. This type of roofing shall be composed of one layer approximately 30 lb. asphalt rag felt, two layers approximately 14 lb. asphalt impregnated asbestos felt, and a minimum of 85 lb. asphalt per 100 sq. ft.

3. Lay sheets of asphalt saturated rag felt, weighing approximately 30 lb. per 108 sq. ft., directly over the sheathing. Lap the joints 2 inches and seal them with asphalt. Nail these sheets along the lap with barbed nails driven through tin caps, spaced 6 inches apart, and in parallel lines approximately 10 inches apart and approximately 10 inches from the laps; these nails to be spaced 18 inches apart and staggered. This 30-lb. felt shall be laid parallel to pitch of roof and turned up 6 inches above roof deck at all vertical surfaces, but not cemented to vertical surfaces.

4. Over the 30 lb. rag felt apply metal eave strips at edges of the roof as specified in paragraph 6, Section 11, Sheet Metal Work.

5. Mop the entire surface of the 30 lb. felt with the asphalt, heated to flow freely, and while hot, embed into it sheets of asphalt impregnated asbestos felt, weighing not less than 14 lb. per 108 sq. ft. in two-ply construction; this 14 lb. felt to be run at right angles to the 30-lb. felt, lapped 17 inches for 32-inch wide felt and 19 inches for 36-inch wide felt and turned up 6 inches above roof deck at all vertical surfaces.

Mop the entire surface between plies with asphalt heated to flow freely, and roll the felts closely behind the mop so that no missing of asphalt can possibly take place. Approximately 30 lb. of asphalt shall be used per square for each mopping.

Nail the upper edge of each sheet with the barbed nails, driven through tin caps spaced 9 inches apart; the center line of nail heads to be approximately  $\frac{3}{4}$  inch below back edge of sheet.

6. Flashings shall be installed at all intersections of the roof with vertical surfaces, and the plans will show whether sheet metal or felt flashings shall be used.

Where sheet metal flashings are called for, they shall be furnished and installed in accordance with paragraph 4, Section 11, Sheet Metal Work, and shall consist of a metal base and counter flashing, installed after the application of the last two plies of felt but before the final coating of asphalt is applied. The flange of the base flashing on the roof deck shall be coated with hot asphalt, into which shall be bedded a 4-inch strip of 14-lb. asbestos felt, centered over the nailing course. This strip shall be coated with hot asphalt into which shall be bedded a second strip of felt, 6 inches wide completely covering the first.

Where felt flashings are called for they shall consist of a base flashing of an approved special asbestos flashing material, cemented to the vertical surface and the roof deck with hot asphalt, and a cap flashing of the same material turned into masonry walls not less than 4 inches and extending down to the roof deck, and cemented to the base flashing, and coated with an approved elastic roofing cement reinforced with mineral fiber. The base flashing shall extend 4 inches out on the roof deck and not less than 8 inches up the vertical surface and the upper edge shall be nailed to the vertical surface where nailing is possible. Brick or concrete walls shall be coated with asphalt primer before the flashing is installed. The edge of the base flashing on the roof shall be covered with a 4-inch strip of 14-lb. asbestos felt embedded in and coated with hot asphalt. End laps of base and cap flashing shall be 3 inches, with joints broken.

7. When the roof is otherwise complete, cover the entire surface with a mopping of asphalt, using not less than 25 lb. of asphalt per 100 sq. ft. of roof surface.

## TYPE C-2 (CLASS 2)

**Asphalt Impregnated Asbestos Felt and Asphalt (Smooth Surface) Over Homogeneous Roofs Cast in Place**

1. This type of roofing shall be limited to use on roof decks having a slope not greater than 6 inches per foot for gypsum or other surfaces that will permit nailing and to slopes not greater than 3 inches per foot for concrete, unless provision is made in the concrete for nailing. Provision for expansion shall be made in covering over expansion joints in concrete slabs.

2. This type of roofing shall be composed of one coat asphalt primer, one coat gallon over primer, one layer, approximately 60 lb., and two layers approximately 14 lb. asphalt impregnated asbestos felt and a minimum of 115 lb. asphalt per 100 sq. ft., not including primer.

3. Coat the concrete or gypsum with cold asphalt primer, using approximately one gallon over concrete and one to two gallons over gypsum per 100 sq. ft. of roof surface to provide a proper bond between roof deck and asphalt. Allow the primer to dry.

4. Mop the entire surface thus primed with asphalt, using approximately 30 lb. per 100 sq. ft., heated to flow freely, and while the cement is hot embed into it sheets of asphalt impregnated asbestos felt, weighing approximately 60 lb. per 108 sq. ft. Lap the joints 2 inches and seal them with hot asphalt. The 60 lb. felt shall be laid parallel to pitch of roof and turned up 6 inches above roof deck on all vertical surfaces.

5. Over the 60-lb. felt apply metal eave strips at all edges of the roof as specified in paragraph 6, Section 11, Sheet Metal Work.

6. Mop the entire surface of the 60-lb. felt with hot asphalt, and while hot embed into it sheets of asphalt impregnated asbestos felt, weighing not less than 14 lb. per 108 sq. ft. in two-ply construction; this 14 lb. felt to be run at right angles to the 60 lb. felt, lapped 17 inches for 32-inch wide felt and 19 inches for 36-inch wide felt and turned up 6 inches above roof deck at all vertical surfaces.

Mop the entire surface between plies with asphalt, heated to flow freely, and roll the felts closely behind the mop so that no missing of asphalt can possibly take place. Approximately 30 lb. of asphalt shall be used per square for each mopping.

7. On gypsum and other types of roof decks that permit of nailing, the back edges of all felts shall be securely nailed to roof slab with cut nails driven through tin caps in addition to mopping.

8. Flashings shall be installed at all intersections of the roof with vertical surfaces, and the plans will show whether sheet metal or felt flashings shall be used.

Where sheet metal flashings are called for, they shall be furnished and installed in accordance with paragraph 4, Section 11, Sheet Metal Work, and shall consist of a metal base and counter flashing, installed after the application of the last two plies of felt but before the final coating of asphalt is applied. The flange of the base flashing on the roof deck shall be coated with hot asphalt, into which shall be bedded a 4-inch strip of 14 lb. asbestos felt, centered over the nailing course. This strip shall be coated with hot asphalt into which shall be bedded a second strip of felt, 6 inches wide completely covering the first.

Where felt flashings are called for they shall consist of a base flashing of an approved special asbestos flashing material, cemented to the vertical surface and the roof deck with hot asphalt, and a cap flashing of the same material turned into masonry walls not less than 4 inches and extending down to the roof deck, and cemented to the base flashing, and coated with an approved elastic roofing cement reinforced with mineral fiber. The base flashing shall extend 4 inches out on the roof deck and not less than 8 inches up the vertical surfaces, and the upper edge shall be nailed to the vertical surface, where nailing is possible. Brick or concrete walls shall be coated with asphalt primer before the flashing is installed. The edge of the base flashing on the roof shall be covered with a 4-inch strip of 14-lb. asbestos felt, embedded in and coated with hot asphalt. End laps of base and cap flashing shall be 3 inches with joints broken.

9. When the roof is otherwise complete, cover the entire surface with a mopping of hot asphalt, using not less than 25 lb. of asphalt per 100 sq. ft. of roof surface.

## TYPE C-2 (CLASS 3)

**Asphalt Saturated Rag Felt, Asphalt Impregnated Asbestos Felt and Asphalt (Smooth Surface) Over Homogeneous Units Cast in Place**

1. This type of roofing shall be limited to use on roof decks having a slope not greater than 6 inches per foot for gypsum or other surfaces that will permit nailing and to slopes not greater than 3 inches per foot for concrete, unless provision is made in the concrete for nailing. Provision for expansion shall be made in covering over expansion joints in concrete slabs.

2. This type of roofing shall be composed of one coat of asphalt primer, one coat asphalt over primer, one layer approximately 30 lb. asphalt rag felt and two layers approximately 14 lb. asphalt impregnated asbestos felt, and a minimum of 115 lb. asphalt per 100 sq. ft., not including primer.

3. Coat the concrete or gypsum with asphalt primer, using approximately 1 gallon over concrete and not less than 1 gallon over gypsum per 100 sq. ft. to provide a proper bond between roof deck and asphalt. Allow the primer to dry.

4. Mop the entire surface thus primed with asphalt, heated to flow freely, and while hot, embed in it sheets of asphalt rag felt, weighing approximately 30 lb. per 108 sq. ft. Lap the joints 2 inches and seal them with hot asphalt. This 30-lb. felt shall be laid parallel to pitch of roof and turned up 6 inches above roof deck at all vertical surfaces.

5. Over the 30-lb. felt apply metal eave strips at all edges of the roof as specified in paragraph 6, Section 11, Sheet Metal Work.

6. Mop the entire surface of the 30-lb. felt with hot asphalt, and while hot, embed into it sheets of asphalt impregnated asbestos felt, weighing not less than 14 lb. per 108 sq. ft. in two-ply construction; this 14 lb. felt to be run at right angles to the 30-lb. felt, lapped 17 inches for 32-inch wide felt and 19 inches for 36-inch wide felt and turned up 6 inches above roof deck at vertical surfaces.

Mop the entire surface between plies with the asphalt, heated to flow freely, and roll the felts closely behind the mop so that no missing of asphalt can possibly take place. Approximately 30 lb. of asphalt shall be used per 100 sq. ft. for each mopping.

7. On gypsum and other types of roof decks that permit of nailing, the back edges of all felt shall be securely nailed to roof slab with cut nails driven through tin caps in addition to mopping.

8. Flashings shall be installed at all intersections of the roof with vertical surfaces, and the plans will show whether sheet metal or felt flashings shall be used.

Where sheet metal flashings are called for, they shall be furnished and installed in accordance with paragraph 4, Section 11, Sheet Metal Work, and shall consist of a metal base and counter flashing, installed after the application of the last two plates of felt but before the final coating of asphalt is applied. The flange of the base flashing on the roof deck shall be coated with hot asphalt, into which shall be bedded a 4-inch strip of 14 lb. asbestos felt, centered over the nailing course. This strip shall be coated with hot asphalt into which shall be bedded a second strip of felt, 6 inches wide completely covering the first.

Where felt flashings are called for they shall consist of a base flashing of an approved special asbestos flashing material, cemented to the vertical surface and the roof deck with hot asphalt, and a cap flashing of the same material turned into masonry walls not less than 4 inches and extending down to the roof deck, and cemented to the base flashing, and coated with an approved elastic roofing cement reinforced with mineral fiber. The base flashing shall extend 4 inches out on the roof deck and not less than 8 inches up the vertical surfaces, and the upper edge shall be nailed to the vertical surface, where nailing is possible. Brick or concrete walls shall be coated with asphalt primer before the flashing is installed. The edge of the base flashing on the roof shall be covered with a 4-inch strip of 14 lb. asbestos felt, embedded in and coated with hot asphalt. End laps of base and cap flashing shall be 3 inches, with joints broken.

9. When the roof is otherwise complete, cover the entire surface with a mopping of hot asphalt, using not less than 25 lb. of asphalt per 100 sq. ft. of roof surface.

**4. Guarantee**

The contractor shall furnish an unqualified guarantee, with good and sufficient bond covering the maintenance of the entire roof and all flashing in a watertight condition for a period of years from date of completion and acceptance of the entire roof.

## 5. General Conditions

All materials entering into the work and all methods used by the contractor shall be subject to the approval of the Engineer and no part of the work will be considered as finally accepted until all of the work is completed and accepted.

The General Conditions as given in Section 1 of this specification shall be considered to apply with equal force to this section of the specification.

## Appendix B

### (2) PREPARATION OF SPECIFICATIONS FOR RAILWAY BUILDINGS

F. R. Judd, Chairman, Sub-Committee; J. N. Grim, E. L. Haberle, L. C. Hinsch, A. C. Irwin, O. M. Rognan.

The Committee submits for publication in the Manual, Specifications for Electrically Operated Freight or Baggage Elevators, previously published in the Proceedings as part of Appendix A, Section 29, pages 682 to 688, both inclusive, of Bulletin 354, Vol. 34, Proceedings 1933.

The following specifications are submitted at this time for publication in the Proceedings as information for criticism:

Section 30-D, Steel Chimneys—Welded.

Section 30-E, Genuine Wrought Iron Chimneys.

Section 10-D, Built-up Roofing, Type C-1 (Class 1).

Asphalt Impregnated Asbestos Felt and Asphalt (Smooth Surface) over Wood or Pre-cast Units.

Built-up Roofing, Type C-2 (Class 1).

Asphalt Impregnated Asbestos Felt and Asphalt (Smooth Surface) over Homogeneous Roofs Cast-in-place.

Section 31-A, Wood Screens.

Section 31-B, Metal Screens.

The Committee now has in course of preparation a specification for Genuine Wrought Iron Chimneys—Welded, and has under consideration the preparation of a specification for Reinforced Brick Chimneys. The Committee also has under consideration the revising of specifications for Asphalt Impregnated Felt Roofing over Wood or Pre-cast Gypsum and over Concrete or Poured Gypsum, Section 10-D, Types D-1 and D-2, published in Bulletin 323, January, 1930. The revisions are necessary in order that these specifications might agree in form and arrangement with those referred to in the foregoing Appendix A.

## SPECIFICATIONS FOR BUILDINGS FOR RAILWAY PURPOSES

### Section 30-D

#### STEEL CHIMNEYS—WELDED

##### 1. General

The contractor shall completely design and shall furnish all labor, material, tools and equipment, and construct a steel chimney of the height and diameter shown on drawings and as specified. The chimney shall be either self-supporting, guyed or stayed as shown on drawings and as specified.

##### 2. Design

See Section 30-A, Steel Chimneys. Article 2.

### 3. Unit Stresses

The chimney and its foundations shall be so designed that the following unit stresses shall not be exceeded:

The stresses in welds shall be considered on net sections through the throat of the weld, excluding any reinforcement.

Fillet welds placed transverse to the direction of stress shall be considered as under shear.

|                                                        |                                 |                 |
|--------------------------------------------------------|---------------------------------|-----------------|
| Shear on net section through throat of weld.....       | 11,300                          | lb. per sq. in. |
| Tension on net section through throat of weld.....     | 15,000                          | " " " "         |
| Compression on net section through throat of weld..... | 15,000                          | " " " "         |
| Tension in steel plates (net section).....             | 12,000                          | " " " "         |

| $\frac{9}{16}$ " | " —4500     | " " " "              |
| $\frac{5}{8}$ "  | " —5000     | " " " "              |

### 4. Foundation

See Section 30-A, Steel Chimneys. Article 4.

### 5. Excavation

See Section 30-A, Steel Chimneys. Article 5.

### 6. Concrete

See Section 30-A, Steel Chimneys. Article 6.

### 7. Steel

See Section 30-A, Steel Chimneys. Article 7.

### 8. Welding

If the chimney is to be assembled before it is erected, it shall be temporarily braced or designed to properly withstand all stresses that may occur while it is being handled and during the process of erection.

Finished chimneys shall be true to line, free from twists, bends and open joints, and shall be gas tight.

The Contractor designing or supervising the chimney shall be experienced and skilled in such work.

Contractors shall satisfy the Engineer that they can meet the qualification tests and furnish satisfactory materials and equipment to be used on the proposed work.

The weld metal shall be sound throughout and be free from excessive oxides, slag inclusion and gas pockets.

The weld metal shall penetrate into the root of the joint.

The weld metal shall be thoroughly fused with the base metal along all surfaces and edges of union. Uniform fusion with base metals of unequal thickness shall be obtained by playing the arc or flame a proportionately longer time upon the thicker material.

The surface of welds shall be reasonably smooth and uniform in contour. The depth of the crater at the terminus of weld shall not be less than  $\frac{1}{8}$ -inch.

The weld metal along the toe of the weld shall not overlap the base metal surface, but shall form an intimate contact therewith.

The base metal along the toe of the weld shall not be reduced in thickness by the welding operation.

Adequate platform or scaffolding shall be provided to permit favorable welding conditions and to insure the safety of the welders.

The operator, while welding, shall be protected from the rays by suitable equipment provided for the purpose.

The arrangement of the joints to be welded shall be such as to enable the welder to have an unobstructed view of the surfaces to be welded during the welding operation.

When tack welds are located in the path of designed welds, they shall, during the welding operation, be either melted out or fused in with the final weld.

Proper fusion, penetration and soundness of weld shall be secured by using as short an arc as can be maintained for each form of weld.

In gas welding, unless otherwise specified, always use a neutral flame.

Surfaces to be welded shall be free from loose mill scale, rust, paint or other foreign matter. A thin coat of linseed oil or equivalent, over the surfaces to be welded, need not be removed. This provision applies both in the case of new structures and where new material is to be welded to material in an existing structure.

In assembling and during welding, the component parts of a built up member shall be held by sufficient clamps or other adequate means to hold the parts in proper relation for welding.

For structures over 30 (thirty) feet in height, erection bolts or equivalent means shall be employed for temporarily supporting the members.

Proper alinement of the various members shall be made before connections are welded.

All electrodes, welding wire and welding rods shall be of a good, approved grade, such as recommended by the American Welding Society in its Code for Fusion Welding and Gas Cutting in Building Construction, which in the hands of an experienced welder shows good weldability in flat, vertical and overhead positions.

Plates forming the shell of the chimney shall be slightly conical so that the upper ring will always fit inside of the section below. Vertical seams shall be so located as to break joints. Lap joints shall be used for circumferential seams and butt joints shall be used for vertical seams.

The circumferential laps shall have a full strength fillet weld on the outside. A caulk weld bead shall be placed on the inside lap to insure gas-tightness.

One or both edges of base metal parts,  $\frac{1}{4}$ -inch or more in thickness, transmitting stress by means of butt welds shall be beveled. For single and double vee joints, the bevel of each part shall be not less than thirty degrees ( $30^\circ$ ), thus forming an open space with an angle of not less than sixty degrees ( $60^\circ$ ). For single and double bevel joints, the bevel shall be not less than forty-five degrees ( $45^\circ$ ). Before welding, the root edge or face of one part shall be separated from the root edge or face of the other part.

All butt welds shall be reinforced by depositing additional metal on the weld to a height extending beyond the surface of the thinnest part joined. The height of said reinforcement shall be not less than the following percentages of the thickness of the thinnest part joined: twenty per cent (20%) for single vee and single bevel butt welds, and twelve and one-half per cent ( $12\frac{1}{2}\%$ ) on each side for double vee and double bevel butt welds.

**9. Details of Work**

See Section 30-A, Steel Chimneys. (Paragraphs 1, 5, 6 and 7 only of Article 8)

**10. Accessories**

See Section 30-A, Steel Chimneys. Article 9.

**11. Breaching Opening**

See Section 30-A, Steel Chimneys. Article 10.

**12. Cleanout Door**

See Section 30-A, Steel Chimneys. Article 11.

**13. Painter's Collar**

See Section 30-A, Steel Chimneys. Article 12.

**14. Grounding for Lightning Protection**

See Section 30-A, Steel Chimneys. Article 13.

**15. Chimney Lining**

See Section 30-A, Steel Chimneys. Article 14.

**16. Ladder**

See Section 30-A, Steel Chimneys. Article 15.

**17. Draft Gage**

See Section 30-A, Steel Chimneys. Article 16.

**18. Pyrometer**

See Section 30-A, Steel Chimneys. Article 17.

**19. Painting**

All steel shall be cleaned of dirt, rust and scale and all surfaces, except those which would affect the successful welding of the members, shall be given a shop coat of red lead and linseed oil. After erection, the chimney shall receive two (2) coats of an approved paint.

**20. Guarantee**

See Section 30-A, Steel Chimneys. Article 19.

**21. General Conditions**

All material entering into the work and all methods used by the Contractor shall be subject to the approval of the engineer, and no part of the work will be considered as finally accepted until all of the work is completed and accepted.

The General Conditions in Section 1 of these specifications shall apply with equal force in this section of the specifications.

**Section 30-E****GENUINE WROUGHT IRON CHIMNEYS****1. General**

The contractor shall completely design and shall furnish all labor, material, tools and equipment, and construct a genuine wrought iron chimney of the height and diameter shown on drawings and as specified. The chimney shall be either self-supporting, guyed or stayed, as shown on drawings and as specified.

## 2. Design

See Section 30-A, Steel Chimneys. Article 2.

## 3. Unit Stresses

The chimney and its foundations shall be so designed that the following unit stresses shall not be exceeded:

|                                                       |                                                                    |
|-------------------------------------------------------|--------------------------------------------------------------------|
| Tension in genuine wrought iron plates.....           | 12,000 lb. per sq. in. net section                                 |
| Compression in genuine wrought iron plates.....       | 10,000 lb. per sq. in. gross section                               |
| Shear in genuine wrought iron rivets and plates....   | 9,000 lb. per sq. in.                                              |
| Bearing on genuine wrought iron rivets and plates.... | 18,000 lb. per sq. in.                                             |
| Extreme fiber in bending.....                         | 12,000 lb. per sq. in.                                             |
| Tension in genuine wrought iron anchor bolts.....     | 14,000 lb. per sq. in. net section                                 |
| Tension in steel guys.....                            | $\frac{1}{2}$ ultimate strength                                    |
| Tension in genuine wrought iron stays.....            | 14,000 lb. per sq. in. net section                                 |
| Compression in genuine wrought iron stays.....        | 18,000—60 $l/r$ per sq. in. (not to exceed 14,000 lb. per sq. in.) |

2000 pound concrete, compression ..... 400 lb. per sq. in.

2000 pound concrete, shear ..... 60 lb. per sq. in.

Reinforcing steel, tension (intermediate grade)..... 18,000 lb. per sq. in.

Reinforcing steel, bond, deformed bars..... 100 lb. per sq. in.

Reinforcing steel, bond, plain bars..... 80 lb. per sq. in.

Ratio moduli elasticity steel and concrete = 15

$l$  = length of member in inches.

$r$  = least radius of gyration of member in inches.

Bearing on soil, determined by local conditions.

Pile loading, determined by local conditions.

## 4. Foundation

See Section 30-A, Steel Chimneys. Article 4.

## 5. Excavation

See Section 30-A, Steel Chimneys. Article 5.

## 6. Concrete

See Section 30-A, Steel Chimneys. Article 6.

## 7. Materials and Workmanship

All plates shall be of genuine wrought iron in accordance with the American Society for Testing Materials Specification A-42 and subsequent revisions thereof.

All anchor bolts, bars and structural shapes shall be of genuine wrought iron in accordance with the American Society for Testing Materials Specification A-41 and subsequent revisions thereof, which is the standard specification for refined wrought iron bars.

All rivets shall be made from genuine wrought iron, in accordance with the current specifications of the American Society for Testing Materials.

Finished chimneys shall be true to line, free from twists, bends and open joints, and shall be gas tight.

All workmanship shall comply with the standard specification for structural steel and iron, Section 12-A of these specifications, unless otherwise specified.

## 8. Details of Iron Work

See Section 30-A, Steel Chimneys. Article 8. Substitute the phrase "genuine wrought iron" for the word "steel".

## 9. Accessories

See Section 30-A, Steel Chimneys. Article 9.

## 10. Breeching Opening

See Section 30-A, Steel Chimneys. Article 10.

**11. Cleanout Door**

See Section 30-A, Steel Chimneys. Article 11. Substitute the phrase "genuine wrought iron" for the word "steel".

**12. Painter's Collar**

See Section 30-A, Steel Chimneys. Article 12. Substitute the phrase "genuine wrought iron" for the words "structural steel".

**13. Grounding for Lightning Protection**

See Section 30-A, Steel Chimneys. Article 13.

**14. Chimney Lining**

See Section 30-A, Steel Chimneys. Article 14.

**15. Ladder**

See Section 30-A, Steel Chimneys. Article 15. Substitute the phrase "genuine wrought iron" for the word "steel".

**16. Draft Gage**

See Section 30-A, Steel Chimneys. Article 16.

**17. Pyrometer**

See Section 30-A, Steel Chimneys. Article 17.

**18. Painting**

See Section 30-A, Steel Chimneys. Article 18. Substitute the phrase "genuine wrought iron" for the word "steel".

**19. Guarantee**

See Section 30-A, Steel Chimneys. Article 19.

**20. General Conditions**

All materials entering into the work and all methods used by the Contractor shall be subject to the approval of the Engineer, and no part of the work will be considered as finally accepted until all of the work is completed and accepted.

The General Conditions in Section 1 of these specifications shall apply with equal force to this article of the specification.

**Section 10-D****BUILT-UP ROOFING****TYPE C-1 (CLASS 1)****Asphalt Impregnated Asbestos Felt and Asphalt (Smooth Surface) Over Wood or Pre-Cast Units**

1. This type of roofing shall be limited to roof decks having a slope not greater than 6 inches per foot for wood and pre-cast gypsum and to a slope not greater than 3 inches per foot for pre-cast concrete, unless provision is made in the pre-cast concrete units for nailing.

2. This type of roofing shall be composed of one layer approximately 60 lb., three layers not less than 14 lb. asphalt impregnated asbestos felt and a minimum of 115 lb. of asphalt per 100 sq. ft.

3. Lay sheets of asphalt impregnated asbestos felt weighing approximately 60 lb. per 108 sq. ft. directly over the sheathing. Lap the joints 2 inches and seal them with

asphalt. Nail these sheets along the lap with barbed nails driven through tin caps spaced 6 inches apart and in parallel lines approximately 10 inches apart and approximately 10 inches from the laps, these nails to be spaced 18 inches apart and staggered. This 60 lb. felt shall be laid parallel to the pitch of the roof and turned up 6 inches above roof deck at all vertical surfaces, but not cemented to vertical surfaces.

4. Over the 60 lb. felt, apply metal eave strips at edges of the roof as specified in paragraph 6, Section 11, Sheet Metal Work.

5. Mop the entire surface of the 60 lb. felt with the asphalt, heated to flow freely, and while hot, embed into it sheets of asphalt impregnated asbestos felt, weighing not less than 14 lb. per 108 sq. ft. in three ply construction; this 14 lb. felt to be run at right angles to the 60 lb. felt, lapped 22 inches for 32-inch wide felt and 25 inches for 36-inch wide felt, and turned up 6 inches above roof deck at all vertical surfaces.

Mop the entire surface between plies with asphalt, heated to flow freely, and roll the felts closely behind the mop, so that no missing of asphalt can possibly take place. Approximately 30 lb. of asphalt shall be used per square for each mopping.

Nail the upper edge of each sheet with the barbed nails, driven through tin caps spaced 9 inches apart; the center line of nail heads to be approximately  $\frac{3}{4}$  inch below back edge of sheet.

6. Flashing shall be installed at all intersections of the roof with vertical surfaces and the plans will show whether sheet metal or felt flashings shall be used.

Where sheet metal flashings are called for, they shall be furnished and installed in accordance with paragraph 4, Section 11, Sheet Metal Work, and shall consist of a metal base and counter flashing, installed after the application of the last three plies of felt, but before the final coating of asphalt is applied. The flange of the base flashing on the roof deck shall be coated with hot asphalt, into which shall be bedded a 4-inch strip of 14 lb. asbestos felt, centered over the nailing course. This strip shall be coated with hot asphalt, into which shall be bedded a second strip of felt, 6 inches wide, completely covering the first.

Where felt flashings are called for, they shall consist of a base flashing of an approved special asbestos flashing material, cemented to the vertical surface and the roof deck with hot asphalt, and a cap flashing of the same material turned into masonry walls not less than 4 inches and extending down to the roof deck and cemented to the base flashing and coated with an approved elastic roofing cement, reinforced with mineral fiber. The base flashing shall extend 4 inches out on the roof deck and not less than 8 inches up the vertical surface and the upper edge shall be nailed to the vertical surface where nailing is possible. Brick or concrete walls shall be coated with asphalt primer before the flashing is installed. The edge of the base flashing on the roof shall be covered with a 4 inch strip of 14 lb. asbestos felt, embedded in and coated with hot asphalt. End laps of base and cap flashing shall be 3 inches, with joints broken.

7. When the roof is otherwise complete, cover the entire surface with a mopping of hot asphalt, using not less than 25 lb. of asphalt per 100 sq. ft. of roof surface.

## Section 10-D

### BUILT-UP ROOFING

#### TYPE C-2 (CLASS 1)

#### Asphalt Impregnated Asbestos Felt and Asphalt (Smooth Surface) Over Homogeneous Roofs Cast in Place

1. This type of roofing shall be limited to use on roof decks having a slope not greater than 6 inches per foot for gypsum or other surfaces that will permit nailing and to slopes not greater than 3 inches per foot for concrete, unless provision is made in the concrete for nailing. Provision for expansion shall be made in covering over expansion joints in concrete slabs.

2. This type of roofing shall be composed of one coat asphalt primer, one coat asphalt over primer, one layer, approximately 60 lb., and three layers not less than 14 lb. asphalt impregnated asbestos felt and a minimum of 145 lb. asphalt per 100 sq. ft., not including primer.

3. Coat the concrete or gypsum with cold asphalt primer, using approximately one gallon over concrete and one to two gallons over gypsum per 100 sq. ft. of roof surface, to provide a proper bond between roof deck and asphalt. Allow the primer to dry.

4. Mop the entire surface thus primed with asphalt, using approximately 30 lb. per 100 sq. ft., heated to flow freely, and while hot, embed into it sheets of asphalt impregnated asbestos felt, weighing approximately 60 lb. per 108 sq. ft. Lap the joints 2 inches and seal them with hot asphalt. The 60 lb. felt shall be laid parallel to pitch of roof and turned up 6 inches above roof deck on all vertical surfaces.

5. Over the 60 lb. felt apply metal eave strips at all edges of the roof as specified in paragraph 6, Section 11, Sheet Metal Work.

6. Mop the entire surface of the 60 lb. felt with hot asphalt and while hot, embed into it sheets of asphalt impregnated asbestos felt, weighing not less than 14 lb. per 108 sq. ft., in 3 ply construction; this 14 lb. felt to be run at right angles to the 60 lb. felt, lapped 22 inches for 32-inch wide felt and 25 inches for 36-inch wide felt and turned up 6 inches above roof deck at all vertical surfaces.

Mop the entire surface between plies with asphalt, heated to flow freely and roll the felts closely behind the mop, so that no missing of asphalt can possibly take place. Approximately 30 lb. of asphalt shall be used per square for each mopping.

7. On gypsum and other types of roof decks that permit of nailing, the back edges of all felts shall be securely nailed to roof slab with cut nails driven through tin caps in addition to mopping.

8. Flashing shall be installed at all intersections of the roof with vertical surfaces and the plans will show whether sheet metal or felt flashings shall be used.

Where sheet metal flashings are called for, they shall be furnished and installed in accordance with paragraph 4, Section 11, Sheet Metal Work, and shall consist of a metal base and counter flashing, installed after the application of the last three plies of felt, but before the final coating of asphalt is applied. The flange of the base flashing on the roof deck shall be coated with hot asphalt, into which shall be bedded a 4 inch strip of 14 lb. asbestos felt, centered over the nailing course. This strip shall be coated with hot asphalt, into which shall be bedded a second strip of felt, 6 inches wide, completely covering the first.

Where felt flashings are called for, they shall consist of a base flashing of an approved special asbestos flashing material, cemented to the vertical surface and the roof deck with hot asphalt, and a cap flashing of the same material turned into masonry walls not less than 4 inches and extending down to the roof deck and cemented to the base flashing and coated with an approved elastic roofing cement, reinforced with mineral fiber. The base flashing shall extend 4 inches out on the roof deck and not less than 8 inches up the vertical surface and the upper edge shall be nailed to the vertical surface where nailing is possible. Brick or concrete walls shall be coated with asphalt primer before the flashing is installed. The edge of the base flashing on the roof shall be covered with a 4 inch strip of 14 lb. asbestos felt, embedded in and coated with hot asphalt. End laps of base and cap flashing shall be 3 inches, with joints broken.

9. When the roof is otherwise complete, cover the entire surface with a mopping of hot asphalt, using not less than 25 lb. of asphalt per 100 sq. ft. of roof surface.

## Section 31-A

### WOOD SCREENS

#### 1. General

The contractor shall furnish all labor, material, tools and equipment necessary to furnish and place complete all wood screens for windows, transoms and doors, complete with necessary hardware as herein specified and as shown and implied on the drawings.

#### 2. Woodwork

Window, transom and door screens shall be made of kiln dried genuine White Pine. (See Note 1) Woodwork shall be dressed and sanded to a smooth finish. Corners and joints shall be rigid and substantial. Window screens shall be full length type, (See Note 2) frames shall be  $1\frac{1}{8}$  in. thick, (See Note 3) stiles and rails of such widths as to match windows, transoms and doors. Suitable screen moulding shall be used to secure wire cloth to frames.

### 3. Wire Cloth

Wire cloth shall be 16 mesh copper bronze of an approved make. (See Note 4)

### 4. Hardware

Window and transom screens shall be equipped with approved metal hangers, hook and eyes, or other suitable approved type of fasteners. Screen doors shall be equipped with loose pin butts, screen door check, screen door fastener, pull and plate of an approved make. (See Note 5)

Wire cloth in lower portion of screen doors shall be protected from damage by horizontal  $\frac{5}{8}$ " round bars of same finish as hardware, placed on both sides of doors, (See Note 6) to each door, spaced (See Note 7) inches on centers.

### 5. Number Tags

Window, transom and door screens, shall be provided with a duplicate set of non-corrosive metal number tags, one applied to each screen and one to each corresponding opening.

### 6. Finishing

Woodwork of window, transom and door screens shall be painted in accordance with painting and glazing specification. Copper bronze wire cloth (See Note 4) shall not be painted. (See Note 8)

### 7. Shop Drawings

When required by the Engineer and before proceeding with this work, the contractor shall submit for approval of the Engineer, shop or detail drawings covering all wood screen work, together with list of finish hardware to be furnished, make of copper bronze wire cloth, etc. (See Note 4)

### 8. Guarantee

All wood screens shall be guaranteed for the stated period of years given in the contractor's proposal and all or any wood screens shall be replaced by the contractor at his own expense if they prove defective in workmanship, material or operation.

### 9. General Conditions

All materials entering into the work and all methods used by the contractor shall be subject to the approval of the Engineer and no part of the work will be considered as finally accepted until all the work is completed and accepted.

The General Conditions as given in Section 1 of this specification shall be considered to apply with equal force to this section of the specification.

#### NOTES—WOOD SCREENS

(1) Other kinds of woods may be used—change as required for particular work under consideration.

#### WOOD FRAMES

Other kinds of woods used for screen frames, depending upon locality, use and type of building.

Cypress  
Cedars  
Douglas Fir  
Hemlock  
Spruce  
Redwood  
Yellow Poplar  
Southern Pine  
Pondosa Pine  
Birch  
Oaks  
Chestnut

Also veneered hardwoods over wood cores of suitable wood.

(2) Type of window screens vary—substitute type desired for particular work under consideration.

#### TYPE OF SCREENS

Full Screens  
Half Screens  
Double Vertical Sliding Screens  
Single Vertical Sliding Screens  
Hinged Screens, Top and Sides  
Circular Screens for Pivoted Sash  
Double Screens for Pivoted Sash  
Adjustable Screens  
Horizontal Sliding Screens  
Lift-Fold Screens  
Pivoted Screens

(3) Thickness may vary—substitute change desired for particular work under consideration.

(4) Different kinds of wire cloth can be used—substitute change desired for particular work under consideration.

#### WIRE CLOTH

Pure Copper, 99.9 per cent and 99.8 per cent  
Monel Metal  
Bronze  
Copper Bronze 90 per cent  
Mono-Bronze  
Anaconda Bronze  
Black Galvanized  
“Ambrac”—Alloys of nickel and copper  
Electro-galvanized steel wire (Trade names as, “Alumina”, “Gray-Wick”, “Opal”, “Apex”, “Galvanoid”)  
Hot Galvanized  
Galvanized  
Painted Black  
Black Enamel  
Pearl

#### MESHES

Wire cloth meshes used for screen work—12, 14, 16, 18, 20, 24, 40, 60, 100.

(5) Other finish hardware trimming than specified may be desired. Change if so desired.

(6) State number of bars desired.

(7) State centers for spacing of bars.

(8) Finishing may be different than specified, change if desired.

### Section 31-B

#### METAL SCREENS

##### 1. General

The contractor shall furnish all labor, material, tools and equipment necessary to furnish and place complete all metal screens for windows, transoms and doors, complete with necessary hardware as herein specified and as shown and implied on the drawings.

##### 2. Metal Work

Window, transom and door screens shall be (See Note 1) as made by (See Note 2) or other approved equal.

##### 3. Wire Cloth

Wire cloth shall be 16 mesh (See Note 3) of an approved make.

#### 4. Hardware

Window and transom screens shall be equipped with approved metal hangers and suitable approved type of fasteners. Screen doors shall be equipped with loose pin butts, screen door check, screen door fastener, pull and plate of an approved make. (See Note 4)

Wire cloth in lower portion of screen doors shall be protected from damage by horizontal  $\frac{5}{8}$ " round bars of same finish as hardware, placed on both sides of doors, (See Note 5) to each door, spaced (See Note 6) inches on centers.

#### 5. Number Tags

All removable screens for windows, transoms and doors shall be provided with an approved method of numbering. Each screen and opening shall have a corresponding number or designation.

#### 6. Finishing

Finish of all metal screens shall be (See Note 7).

#### 7. Shop Drawings

When required by the Engineer and before proceeding with this work, the contractor shall submit for approval of the Engineer, shop or detail drawings covering all metal screen work, together with samples of construction, hardware, etc.

#### 8. Guarantee

All metal screens shall be guaranteed for the stated period of years given in the contractor's proposal and all or any metal screens shall be replaced by the contractor at his own expense if they prove defective in workmanship, material or operation.

#### 9. General Conditions

All materials entering into the work and all methods used by the contractor shall be subject to the approval of the Engineer and no part of the work will be considered as finally accepted until all the work is completed and accepted.

The General Conditions as given in Section 1 of this specification shall be considered to apply with equal force to this section of the specification.

#### NOTES—METAL SCREENS

- (1) State type of screen to be used for particular work under consideration.

#### METAL FRAMES

Following are some of the kinds of metal used by various manufacturers of metal screens—

- Cold Rolled Steel—Galvanized with pure zinc.
- Cold Rolled Bronze.
- Enameled Galvanized Steel.
- Copper.
- Aluminum Alloy.
- Aluminum.
- Lead Coated Terne Plate Metal.
- Monel Metal.
- Electro-galvanized Copper Bearing Alloy Coated Metal.

#### TYPES OF SCREENS

- Full Screens.
- Half Screens.
- Rolling Screens.
- Double Vertical Sliding Screens.
- Single Vertical Sliding Screens.
- Hinged Screens, Top and Sides.
- Circular Screens for Pivoted Sash.
- Double Screens for Pivoted Sash.
- Adjustable Screens.
- Horizontal Sliding Screens.
- Lift-Fold Screens.
- Pivoted Screens.

(2) Give name and address of manufacturer.

(3) Different kinds of wire cloth can be used—state kind desired, change mesh if desired for particular work under consideration.

#### WIRE CLOTH

Pure Copper, 99.9 per cent and 99.8 per cent

Monel Metal

Bronze

Copper Bronze 90 per cent

Mono-Bronze

Anaconda Bronze

Black Galvanized

"Ambrac"—Alloys of nickel and copper

Electro-galvanized steel wire (Trade name as, "Alumina", "Gray-Wick", "Opal", "Apex", "Galvanoid")

Hot Galvanized

Galvanized

Painted Black

Black Enamel

Pearl

#### MESHES

Wire cloth meshes used for screen work—12, 14, 16, 18, 20, 24, 40, 60, 100.

(4) Other finish hardware trimming than specified may be desired. Change if so desired.

(5) State number of bars desired.

(6) State centers for spacing of bars.

(7) State finish desired for metal frames.

### Appendix C

#### (3) REMODELING FREIGHT HOUSES FOR ACCOMMODATION OF TRUCK DOOR-TO-DOOR DELIVERY OF FREIGHT

A. C. Copland, Chairman, Sub-Committee; A. L. Becker, R. E. Mohr, E. A. Harrison, G. H. Burnette.

All l.c.l. freight is, to all intents and purposes, a door-to-door delivery, either by individual trucks or trucking companies.

Existing freight houses usually have tracks on one or both sides for the loading or unloading of freight cars. Generally, on one side is the tailboard space, with or without platform, for trucks or other vehicles delivering or receiving freight. The same arrangement should meet the requirements of the door-to-door system, consequently it is unnecessary to remodel existing freight houses materially, if any. All that is involved is a change in responsibility and operation.

### Appendix D

#### (4) BUS TERMINAL BUILDINGS, ISOLATED AND IN CONJUNCTION WITH RAILWAY STATIONS

O. G. Wilbur, Chairman, Sub-Committee; C. L. Wenkenbach, E. W. Niblet, J. W. Orrock, C. D. Horton, F. R. Micheal.

Considerable data has been assembled on this subject and a report is being prepared. It is the recommendation that this subject be continued another year.

## Appendix E

**(5) APPLICATION OF STAINLESS AND RUST-RESISTING METALS TO BUILDING CONSTRUCTION**

J. W. Orrock, Chairman, Sub-Committee; F. B. Doolittle, Hugo Filippi, A. B. Stone, C. D. Horton, E. L. Haberle.

Information on this subject is being assembled but sufficient data for incorporation in a report is not yet available. It is recommended that the subject be continued another year.

## Appendix F

**(6) VERMIN AND RAT-PROOFING IN BUILDINGS**

A. H. Morrill, Chairman, Sub-Committee; Hugo Filippi, A. C. Irwin, W. T. Dorrance, L. C. Hinsch, J. A. Stocker.

The Committee reports progress but is not sufficiently prepared to present a tentative report. It is recommended that the subject be continued another year.

## Appendix G

**(7) RELATIVE MERITS OF WOOD AND FIREPROOF ROOF STRUCTURES, WHICH INCLUDES WOOD, HOLLOW TILE FIRE-PROOFING, CONCRETE AND CEMENT TILE, ETC.**

A. T. Upson, Chairman, Sub-Committee; O. M. Rognan, F. B. Doolittle, C. L. Wenkenbach, J. N. Grim, A. C. Irwin, E. Christiansen.

**I—Wood Decks**

**A WOOD SHEATHING, 2 IN. AND THINNER, ON CLOSELY SPACED WOOD RAFTERS.**—This construction is relatively inexpensive. It is combustible, and difficult to protect with sprinklers. It lends itself readily to various types of roof coverings. It is adaptable to small roofs of irregular shapes. It is a fair insulator of heat.

**B WOOD DECKING, 2½ IN. AND THICKER, ON WOOD BEAMS OR PURLINS OF NOT LESS THAN 6 IN. NOMINAL MINIMUM DIMENSION.**—This construction is slow burning and readily protected with sprinklers. It is a good insulator of heat. It can be used with any type of roof covering.

**C WOOD DECKING, 2½ IN. AND THICKER, ON STEEL BEAMS OR PURLINS.**—The wood decking is slow burning, but the combination is of low fire-resisting value because of warping of the steel beams in a fire. It can be equipped with sprinklers. It is a good insulator of heat. The use of steel beams should be avoided when corrosive gases exist.

**D WOOD DECKING, 2½ IN. AND THICKER, ON REINFORCED CONCRETE BEAMS.**—About the same as I-B, except that the reinforced concrete beams are fire-resistive. This provides an insulating deck on fire-resistive supports. It requires more time for erection than the preceding types, except where pre-cast concrete beams are used.

**E ARCHED WOOD ROOFS.**—Proprietary roof types consist of a wooden vault built up of light wooden purlins in a diagonal pattern, or of specially designed panels sheathed with wood. Successful forms of this construction are those built under the designation of "Lamella" construction and "No-Truss" construction. The former is capable of structural analysis; the latter is designed according to empirical rules established by test. All these types require either buttresses or tie rods. They can be used for roofing large areas without columns or trusses. Their appearance and acoustics are good. They are of light weight, easily erected and a fair insulator of heat. They are combustible but can be built in a slow burning type, though not often done.

Laboratory tests of large scale glued laminated timber arches have demonstrated these conform substantially to the elastic theory of arches and can be used for structures of considerable extent.

**F FIREPROOFED WOOD SHEATHING OR DECKING.**—The use of fireproofed wood in any of the above types will increase the fire resistance of the sheathing or decking itself.

## **II—Decks of Various Non-Combustible Materials in Sheets, on Steel Purlins**

Decks of this type are light in weight, can be erected quickly, but while the material is incombustible, the roof is subject to failure from warping or disintegration when exposed to fire and water. If sufficient pitch is provided no other roof covering is required except for insulation. Some types are difficult to make tight against wind-driven snow. In selecting these roofs exposure to corrosive gases and to peculiar atmospheric conditions such as salt air should be considered.

**A BLACK OR GALVANIZED STEEL SHEETS.**—The sheets are 18 or 20 gage with ribs of various shapes formed longitudinally about 4" to 6" centers. This construction is light weight, but requires insulating material if heat losses are to be prevented. An insulating board is desirable on top of the steel decking to prevent buckling and to provide a base for the application of roofing. This type of decking is not suitable for roof coverings that require nailing. It must be painted.

**B CORRUGATED STEEL SHEETS COATED WITH ASPHALT AND ASBESTOS FELT.**—These are suited to buildings not heated which have roofs with proper slope. For heated buildings, additional roof covering and insulation should be provided as under II-A. It does not require painting. It is not suitable for roof coverings that require nailing.

**C CORRUGATED GALVANIZED STEEL SHEETS.**—This type is low in cost, light weight, and not permanent. It has no insulating value. It is not suitable for roof coverings that require nailing.

**D CORRUGATED NON-FERROUS SHEETS.**—This type of roof is durable, if expansion is properly provided for, and is light in weight. It has no insulating value. No roof covering or painting is required. It is not suitable for roof coverings that require nailing.

**E CORRUGATED ASBESTOS SHEETS.**—This type of roof needs no painting, and has some insulating value. The sheets are relatively brittle and not suitable for structures subject to severe vibration or impact.

## **III—Concrete Decks**

Concrete decks can be covered, where required, with any type of roofing; where nailing is required, a nailing composition finish may be applied or nailing strips embedded in the concrete. They are durable when properly designed and constructed. Light weight aggregate may be used to reduce weight and increase insulation. Climatic or use conditions may require insulation.

**A CAST-IN-PLACE SLABS ON UNPROTECTED STEEL BEAMS.**—This construction is non-combustible, but not fire-resistive. It requires more time to construct than pre-cast slabs, but shores are not necessary. It is a heavy type.

**B CAST-IN-PLACE SLABS ON PROTECTED STEEL BEAMS.**—This is fire-resistive. It requires more form work than "A", and for other than concrete protection requires more time for erection. It is a heavy type.

**C CAST-IN-PLACE SLABS ON REINFORCED CONCRETE BEAMS.**—This is fire-resistive. Construction is slower than "A" and shores may interfere with other work. It is heavier than "A" and for long spans heavy supporting members are required.

**D CAST-IN-PLACE "FLAT SLAB" CONSTRUCTION.**—This has high fire resistance. It provides a ceiling free from beams. Shores are ordinarily used in construction.

**E CAST-IN-PLACE CONCRETE T-BEAMS.**—This is fire-resistive. Shores are required for construction. The use of hollow tile fillers increases the insulating value and provides a flat ceiling.

**F PRE-CAST CONCRETE SLABS ON UNPROTECTED STEEL BEAMS.**—This is non-combustible but not fire-resistive. It may be made fire-resistive by protecting the steel beams. Its use allows rapid construction. It is comparatively light in weight.

## **IV—Reinforced Gypsum Deck on Steel Purlins**

This construction is non-combustible but not fire-resistive. It may be made fire-resistive by protecting the steel beams. It is a good insulator, light in weight, can be placed quickly. It must be covered with roofing. It disintegrates in moist conditions.

**A POURED IN PLACE WITH REMOVABLE FORMS.**—This is the simplest type. Time is required to move forms. Purlin spacing may be varied to suit building conditions.

**B POURED IN PLACE WITH PERMANENT FORMS.**—Has a time advantage over "A" but trouble has been experienced in moist situations from disintegration of "permanent" form material.

**C PRE-CAST GYPSUM SLABS.**—These are available in various sizes and thicknesses, solid and hollow. They have the advantages of quicker erection and cleanliness over types "A" and "B".

### V—Long Span Interlocking Slabs

They must be laid on slopes steep enough to provide sufficient drainage. They can be insulated on the under side. Erection of these slabs is quickly done.

**A INTERLOCKING CONCRETE SLABS ON UNPROTECTED STEEL PURLINS.**—This is non-combustible but is not fire-resistive. The weight may be reduced by using light weight aggregate.

**B INTERLOCKING CAST IRON PLATES ON UNPROTECTED STEEL PURLINS.**—This is non-combustible but is not fire-resistive.

#### RELATIVE MERITS OF DIFFERENT TYPES OF ROOF STRUCTURES

The ratings below represent an approximate gradation from those types of roofs which are indicated to possess the property in question to the greatest degree (Class 1) to those types which possess that property in lesser degree (Class 3), when compared under similar quality of construction and use conditions.

| Type of Roof | Fire Resistance | Insulation Qualities | Durability | Economy of Construction | Rapidity of Construction | Economy of Maintenance | Ease of Alterations | Lighting Qualities | Appearance | Resistance to Corrosive Gases | Resistance to Earthquake Damage | Resistance to Tornado Damage |
|--------------|-----------------|----------------------|------------|-------------------------|--------------------------|------------------------|---------------------|--------------------|------------|-------------------------------|---------------------------------|------------------------------|
| I A          | 3               | 2                    | 2          | 1                       | 1                        | 2                      | 1                   | 3                  | 2          | 1                             | 2                               | 3                            |
| B            | 2               | 1                    | 2          | 1                       | 1                        | 2                      | 1                   | 2                  | 2          | 1                             | 2                               | 2                            |
| C            | 3               | 1                    | 1          | 1                       | 1                        | 2                      | 2                   | 2                  | 2          | 3                             | 2                               | 2                            |
| D            | 2               | 1                    | 2          | 2                       | 2                        | 2                      | 2                   | 2                  | 2          | 2                             | 2                               | 2                            |
| E            | 3               | 2                    | 2          | 2                       | 2                        | 2                      | 2                   | 2                  | 1          | 2                             | 2                               | 2                            |
| II A         | 2               | 3                    | 3          | 1                       | 1                        | 3                      | 1                   | 2                  | 3          | 3                             | 1                               | 3                            |
| B            | 2               | 3                    | 2          | 1                       | 1                        | 2                      | 1                   | 2                  | 2          | 2                             | 1                               | 3                            |
| C            | 2               | 3                    | 2          | 1                       | 1                        | 3                      | 1                   | 2                  | 3          | 3                             | 1                               | 3                            |
| D            | 2               | 3                    | 2          | 1                       | 1                        | 2                      | 1                   | 2                  | 3          | 2                             | 1                               | 3                            |
| E            | 2               | 2                    | 2          | 1                       | 1                        | 2                      | 2                   | 2                  | 2          | 1                             | 3                               | 3                            |
| III A        | 2               | 3                    | 1          | 2                       | 2                        | 2                      | 3                   | 2                  | 2          | 3                             | 2                               | 1                            |
| B            | 1               | 3                    | 1          | 3                       | 3                        | 1                      | 3                   | 2                  | 1          | 1                             | 2                               | 1                            |
| C            | 1               | 3                    | 1          | 3                       | 3                        | 1                      | 3                   | 2                  | 1          | 1                             | 2                               | 1                            |
| D            | 1               | 3                    | 1          | 3                       | 3                        | 1                      | 3                   | 1                  | 1          | 1                             | 1                               | 1                            |
| E            | 1               | 3                    | 1          | 3                       | 3                        | 1                      | 3                   | 2                  | 2          | 1                             | 2                               | 1                            |
| F            | 2               | 3                    | 2          | 2                       | 2                        | 2                      | 2                   | 2                  | 2          | 3                             | 2                               | 1                            |

## Appendix H

### (8) CAUSES OF DUST EXPLOSIONS IN GRAIN ELEVATORS AND METHODS OF OBVIATING THE HAZARD

A. L. Sparks, Chairman, Sub-Committee; R. E. Mohr, F. R. Judd, O. G. Wilbur, E. Christiansen, L. C. Hinsch.

#### Introduction

Since the hauling of grain is one of the principal sources of revenue for American railroads, and being a product that is not likely to be transported in large volume by motor truck, the railroads will necessarily be interested in the storage and handling of

grain indefinitely. Many of the large terminal elevators are owned by the different railroad companies on whose lines they are located, and while they are not generally operated by the railroads, any hazards which imperil human life places heavy responsibility upon the owners.

Quoting from U.S. Department of Agriculture, on Dust Control in Grain Elevators, written by Hylton R. Brown and J. O. Reed:

"From 1919 to February 4, 1933 dust explosions in the United States in plants handling grain and grain products caused the loss of 277 lives, injury to 487 employees, and property damage amounting to more than \$30,000,000. As more than one-fourth of the loss in life and more than one-half of the property damage occurred in grain elevators, special attention has been directed to the elimination of the dust-explosion hazard in the grain elevating industry.

"The requirements for a dust explosion are (1) dust in suspension in air in a certain proportion, and (2) some means of igniting this dust and air mixture. Such explosion, then, may be prevented by using equipment which will eliminate all sources of ignition around the plant, or by controlling the dust and air mixture so that no explosive dust clouds can be formed. For some time attention was directed to the elimination of open flames around plants where it was possible for the explosion hazard to exist. When it was found that electric sparks, blown fuses, broken electric lamps, hot bearings, friction fires, metallic sparks, static electricity, and fires caused by spontaneous combustion could ignite the dust, however, attention was turned to the development of equipment for controlling the dust."

Prior to 1919 considerable attention was given to the study of grain dust explosions on threshing machines in the northwestern wheat belt, by representatives of the Bureau of Chemistry for the U.S. Department of Agriculture and information on early experiments may be found in a bulletin on "Dust Explosions" published by National Fire Protection Association, written by David J. Price and H. H. Brown. Following their campaign a determined effort was made by the Terminal Elevator Grain Merchants Association to find some more successful method for prevention of dust explosion. They conferred with other national organizations and a committee was appointed, the membership of which was made up from representatives of the following organizations:

Mutual Fire Prevention Bureau  
National Board of Fire Underwriters  
National Fire Protection Association  
National Safety Council  
Railway Fire Protection Association  
Terminal Elevator Grain Merchants Association  
Underwriters Grain Association

At a meeting of this committee in Chicago, June 11, 1923, the view was expressed that control of floating dust would lessen explosion hazard probably 75 per cent.

The Bureau of Chemistry, U.S. Department of Agriculture, in their investigations dealing with dust explosions, learned that many of the dust-collecting systems installed in grain elevators throughout the country could not be used or were dismantled because of the objection of the officials having jurisdiction over the weighing of the grain. The weighing departments stated that grain weights are greatly affected by the action of suction used in the collection of the dust. Reports of tests conducted by a number of elevator operators, however, indicated that the weight of the dust removed is almost negligible. Some men experienced in handling grain have stated that less dust is removed by suction than is lost in handling grain by means of poor machinery, with no dust-collecting equipment.

Confronted with these conflicting statements, the Bureau of Chemistry made a study of the effect of dust collection on the weight of grain. The results showed that much depended upon the design and installation of the dust-collecting equipment. In

many cases the equipment seemed to have been installed with no knowledge of the fundamentals of good design. In some cases the claims of weighing departments that grain had been drawn out by improper application of suction to remove the dust at certain points between the car which was being unloaded and the scales, were probably correct. No information concerning a generally accepted method of applying suction or the proper equipment to use could be obtained. Every elevator seemed to have its own system of dust control and no standards existed. None of the systems were so installed as to permit inspection, nor were they so designed that it would be impossible to lift grain by increasing the speed of the fan, with a corresponding increase of suction.

To overcome objection of weighmasters to application of suction apparatus because of the opportunity of removal of grain and lessening of weight, valves have been designed and successfully operated in the air suction trunk lines for controlling the velocity of air. These valves may be set and sealed so that just sufficient air velocity is obtained at suction hoods to take up the dust in suspension and not remove grain. These valves are generally close to the heads.

The results of these investigations showed the necessity for a detailed study of the problems of controlling the dust conditions in grain elevators.

A committee made up of representatives from various national organizations set about conducting experiments and making actual working tests with a view to acquiring information with which to design acceptable dust removal equipment. They arranged with the Van Dusen-Harrington Company, elevator operators, and Day Company, manufacturers of dust collecting devices, for the installation of a test system at Crescent H Elevator in Minneapolis.

A complete report of the installation and test is given in a bulletin entitled, "Removal of Floating Dust in Grain Elevators", published by the National Safety Council, 168 No. Michigan Ave., Chicago. In their test system dust collecting hoods were placed at six principal points as follows:

1. Where car unloading hopper discharges on to belts.
2. Where unloading belt discharges into elevator boot.
3. Where elevator leg buckets pick up grain in boot.
4. Where buckets discharge into spouts at head of legs.
5. Where spouts in head house discharge into garner's.
6. Where valves discharge from garner's on to belts to loaders.

The test was considered successful and the bulletin says the system was approved by the Underwriters Laboratories at Chicago, and by the State Industrial Commission of Minnesota. This installation has been in use since 1924, and is reported by the owners to be still in successful operation.

U.S. Department of Agriculture Bulletin No. 1373, dated February, 1926, describes a recommended system similar to that installed at Crescent H Elevator, and concludes by saying, "Dust collection in grain elevators may not prevent explosions, but it will keep a small dust ignition from developing into a disastrous explosion."

### Methods of Obviating the Hazard

In an effort to attain a higher degree of efficiency in dust control, elevators have been equipped with twin dust collecting hoods at every point where a belt conveyor discharges grain. One hood is placed above the point of discharge to collect dust that would float into the air and the second hood is placed below the discharging belt in such location as will catch the heavier dust that clings to the belt and is dropped on the floor after the belt has discharged and turned on the pulley.

In disastrous general explosions there is seldom, if ever, sufficient evidence left to give a definite clue as to the real cause of the explosion. As has been said, dust in suspension with proper atmospheric conditions may cause explosion from a very small ignition, and since it is impossible entirely to remove dust, even though all floating dust is removed from an elevator building, there still remains danger of an explosion within the elevator legs or boots where new dust is being formed by the constant agitation and friction of the grain.

Leg casings should be provided with ample size vents on the roof, of the same cross-section as the casings. Since explosions will escape at the weakest points, certain types of vents with trap doors on top that open at the instant of the explosion will allow the force to spend itself, preventing severe damage to the casing in the building and lessening the hazard of a general explosion spreading to other parts.

Storage bins should be vented to the roof to provide an outlet for the air displacement during the loading of the bin, otherwise the air, laden with dust in suspension, will find its way into the elevator areas and become a hazard.

The design of the general elevator structure enters largely into the question of minimizing the explosion hazard.

Horizontal surfaces and ledges, inaccessible for cleaning, should be avoided so far as possible, and where necessary, should be inclined as steeply as possible to prevent accumulation of dust.

Interior walls should be finished as smooth as practicable. Experiments have proven that the fine dust that would cling to rough walls is by far more dangerous than the heavier dust.

Large window areas should be introduced wherever practicable and glazed with ordinary glass in such manner as will offer least resistance to release in case of explosion. The greater the areas of light type of construction, the less damage will result from explosion to the heavy concrete construction.

Ignition may be caused by electric sparks, blown fuses, broken lamps, hot bearings, friction fires, metallic sparks, static electricity and spontaneous combustion fires. It has been proved that static electricity is responsible for some explosions, and the National Fire Protection Association in 1929 published a bulletin, "Belt Dressing for Eliminating Static", edited by P. W. Edwards and J. O. Reed, of the U.S. Department of Agriculture, in which the following statements appear:

"Static electrical charges are generated on power transmission belts in three ways: (1) by friction of the belt on the pulley; (2) by separation of the belt from the pulley; (3) to a less extent by the friction of the atmosphere on the belt.

"On conveyor belts the charges are generated by the same means, and in addition by the friction of the conveyed material on the belt.

"Static charges on machinery are caused by—

- (1) Induction.
- (2) Transmission from other sources such as drive pulleys and
- (3) By the friction of the material passing through the machine."

It further states that static electricity can be removed from belts and other surface by grounding systems, humidifying the air sufficiently, ionizing the air in contact with the belt or other surface by means of a gas flame or by the silent discharge of high frequency and high voltage current. Static electricity can be eliminated by special belt dressings.

The bulletin also gives the following formula for a belt dressing:

"A good rubber belt dressing can be prepared by mixing 18 parts of lampblack with 82 parts of good spar varnish. A smaller quantity of lampblack may prevent most of

the cracking which develops after the above dressing is used for several months. The dressing must dry on the belt before running.

"A non-flammable thinner for the varnish can be prepared by mixing equal volumes of carbon tetrachloride and varnish makers' and painters' naphtha.

"A non-static leather belt dressing which has considerable merit consists of 100 cc. liquid fish glue, 80 cc. glycerine, 100 cc. sulphonated castor oil, 170 cc. water, 82 grams lampblack, and 20 cc. of two per cent ammonium hydroxide. These proportions may not be the best for all conditions. In some cases better results will probably be obtained by increasing the quantities of fish glue and glycerine. It may be easily applied with a brush while the belt is moving. It is not necessary for the dressing to dry before running the belt. If the belt has not been properly maintained this dressing will cause the belt to stretch."

### Conclusions

The hazards of dust explosions can be reduced by—

- (1) Good housekeeping to prevent accumulation of static dust.
- (2) Dust-tight electric equipment.
- (3) Plenty of ventilation to prevent atmosphere from becoming charged with explosive dust.
- (4) Dust collection by fan produced suction—to remove dust in suspension at all points where grain is agitated.

"Good Housekeeping" is what the phrase implies—preventing dust accumulations on floors, walls, sills, beams, etc.

It is, of course, very essential that dust-tight cabinets be provided for all switches, fuses, circuit breakers, etc., and all lamps should have vapor proof enclosures.

Plenty of windows, doors, etc., that can be kept open during operation should be provided in grain elevator designs. Special attention should be given to ventilation of basements. Being below ground, with loading and receiving tracks necessarily close to the building, and generally with other buildings on all sides, windows and areaways are reduced to the minimum number and size. Fans should be installed to facilitate basement ventilation.

Scale hoppers and garners should be vented direct through the roof to the open air with vents of ample cross-section. Scale curtains should be tight, with special attention to corner slide levers to prevent dust leakage.

Dust collection is generally performed by means of suction through sheet metal pipes and motor-driven exhaust fans, which take the dust from belt loaders and floor sweeps through dust traps, that permit the grain to fall through and be salvaged, thence to a dust bin from where dust is burned, loaded out or otherwise disposed of.

Where grain weighing authorities object to dust being wasted, it is gathered and sent to the scale on which grain is weighed, or is turned back into the bins.

It is a very easy matter to overload a plant with expensive apparatus which requires so much attention and expert manipulation as to be cumbersome and defeat its own purpose.

Dust removal systems are vital and necessary to the successful operation of modern elevators, but they should be designed and supervised by engineers experienced in elevator ventilation.

One of the important features after the installation of a dust collecting system is to provide the operators of the elevator with proper diagrams and necessary instructions to the men for the successful operation of the system.

Reasonable precautions should be and generally are observed by experienced elevator operators. Warnings should be posted in conspicuous places.

No smoking, no open fires or open lights of any kind should be permitted.

No riveting or hammering against steel should be permitted when dust is in the air. Provision should be made for intercepting tramp iron.

Locomotives with fire in the fireboxes or ashpans should not cross over unloading hoppers, or come near workhouse when air is full of dust.

In designing new elevators the Safety Codes for the Prevention of Dust Explosions, as given in U.S. Department of Labor—Bureau of Labor Statistics, Bulletin No. 562 (or later editions) should be considered.

## Appendix I

### (9) MILL TYPE AND OTHER HEAVY WOOD CONSTRUCTION FOR RAILWAY BUILDINGS

C. L. Wenkenbach, Chairman, Sub-Committee; A. T. Upson, E. W. Niblet, E. K. Mentzer, G. A. Belden, G. H. Burnette, A. B. Stone.

Insufficient data has been assembled for a report on this subject but the Committee reports progress and recommends the subject be continued another year.

## Appendix J

### (10) STUDY THE ECONOMIC VALUE OF VARIOUS BASIC AND COMPOSITE MATERIALS USED IN BUILDING CONSTRUCTION AND MAINTENANCE

W. T. Dorrance, Chairman, Sub-Committee; A. C. Irwin, J. W. Orrock, Hugo Filippi, A. T. Upson, E. A. Harrison, F. R. Judd.

Progress is being made in the study of this subject but is still in the correspondence stage. It is recommended that the subject be continued another year.

### *To the American Railway Engineering Association:*

Your Committee on Grade Crossings presents herewith report on the following subjects:

1. Revision of Manual, including
  - (a) Further study of the proper lighting of the base of signals where located in the center of highway. The Committee reports progress and recommends that the subject be continued.
  - (b) Further study and recommendation in regard to center-road installation of flashing light or wig-wag type of signals. The Committee reports progress and recommends that the subject be continued (Appendix A).
2. Economic aspects of grade crossing protection in lieu of grade separation. The Committee reports progress and recommends that the subject be continued (Appendix B).
3. Recommend standard specifications for street crossings over railway tracks, both steam and electric. Recommended that the Specifications for Preparation of Track Structure, Width of Crossing and Approaches, for Construction of Street Crossings over Railway Tracks, Specifications for the Construction of Rail Type Street Crossings, and Specifications for the Construction of Wood Plank Crossings, be adopted for inclusion in the Manual. It is further recommended that the subject be continued (Appendix C).
4. Relative economy of different types of highway grade crossings. Recommended that the report be received as information (Appendix D).
5. Proper vertical curves on highways for grade separation projects. Recommended that the report be approved for inclusion in the Manual (Appendix E).
6. Investigate the use and report on the merits and economy of "the stop and go" type of signal, with red and green illuminated aspects, as a protective device at highway-railway grade crossings, under usual conditions and special conditions. Recommended that the conclusion be approved (Appendix F).

Respectfully submitted,

THE COMMITTEE ON GRADE CROSSINGS,  
J. G. BRENNAN, *Chairman.*

## Appendix A

### (1) REVISION OF MANUAL, INCLUDING

- (a) Further study of the proper lighting of the base of signals where located in center of highway.

P. M. Gault, Chairman, Sub-Committee; Bernard Blum, H. D. Blake, H. E. Brink, H. M. Church, C. A. Dayton, H. L. Engelhardt, H. W. Fenno, M. V. Holmes, Maro Johnson, R. B. Kittredge, E. R. Lewis, G. P. Palmer, W. C. Pinschmidt, Frank Ringer, Leroy Wyant, A. M. Zabriskie.

#### Conclusion

The Committee reports progress and recommends that the subject be continued.

- (b) Further study and recommendation in regard to center-road installation of flashing light or wigwag type of signals.

#### Conclusion

The Committee reports progress and recommends that the subject be continued.

## Appendix B

### (2) ECONOMIC ASPECTS OF GRADE CROSSING PROTECTION IN LIEU OF GRADE SEPARATION

G. P. Palmer, Chairman, Sub-Committee; S. N. Crowe, L. B. Curtiss, C. A. Dayton, A. R. Dewees, G. N. Edmondson, J. P. Hallihan, W. M. Jaekle, Maro Johnson, R. B. Kittredge, A. E. Korsell, E. R. Lewis, Frank Ringer, A. H. Utter, Leroy Wyant.

The Committee has done considerable work on the subject but is unable to present a final report. It therefore reports progress.

#### Recommendation

It is the recommendation of the Committee that the subject be continued.

## Appendix C

### (3) RECOMMEND STANDARD SPECIFICATIONS FOR STREET CROSSINGS OVER RAILWAY TRACKS, BOTH STEAM AND ELECTRIC

V. R. Walling, Chairman, Sub-Committee; F. D. Batchellor, L. B. Curtiss, A. T. Danver, G. N. Edmondson, C. F. Edwards, H. W. Fenno, P. M. Gault, R. C. Gowdy, J. P. Hallihan, H. A. Hampton, M. V. Holmes, W. M. Jaekle, W. B. Knight, H. M. Shepard, W. L. Young.

The study of this assignment has been carried on the last two years. The preparation of specifications was not sufficiently advanced during the first year for presentation at the 1933 Convention.

This year, four specifications are furnished for your consideration. These have been submitted to the Roadway Committee, American Society of Municipal Engineers and American Transit Association, with whom your Committee has been instructed to collaborate, and no exceptions have been taken.

- (1) Specifications for preparation of track structure, width of crossing and approaches for construction of street crossings over railway tracks.
- (2) Specifications for the construction of rail type street crossings.
- (3) Specifications for the construction of wood plank street crossings.
- (4) Specifications for the construction of highway crossings surfaced with oil processed gravel.

#### (1) SPECIFICATIONS FOR PREPARATION OF TRACK STRUCTURE, WIDTH OF CROSSING AND APPROACHES, FOR CONSTRUCTION OF STREET CROSSINGS OVER RAILWAY TRACKS

##### General

1. These specifications cover drainage, foundation, track work and crossing approaches in connection with construction of street crossings over railway tracks. They must be carried out in detail and with good workmanship.

##### Drainage

2. A requisite for good track is proper drainage, and this shall be provided at all crossings.

Surface ditches shall be installed, if required. Ample sub-drainage with suitable inlets and necessary provisions for clean-out shall be installed to drain thoroughly the sub-grade and prevent formation of water pockets. This drainage shall be connected to a sewer system, if available; if this is not possible connecting metal or concrete pipes shall be installed to carry the water a sufficient distance from the roadbed. Where gravity drainage is not available, a near by sump may prove an economical substitute for an outlet.

Approaches, where feasible, shall be on easy grades descending from the track a sufficient distance that storm water will be carried away from and not onto the tracks.

##### Ballast

3. If track is not well ballasted, or if the ballast is foul, it shall be dug out not less than two feet below bottom of the tie, not less than two feet beyond the ends of the ties and to the first rail joint each way from the crossing, and re-ballasted with good, clean, suitable ballast.

The new ballast shall conform to the American Railway Engineering Association Specifications for Ballast.

##### Track

4. All except sound treated ties shall be replaced with new treated ties. Sawed ties shall be used where the type of the crossing to be installed requires them. All ties shall be tie plated.

Rails throughout the crossing, and for a rail length on each side shall be renewed with new rails of the section standard in that district, unless existing rails are of full standard section.

Rail shall be so placed that there will be no rail joints within the crossing, and with joints preferably located not less than one-half rail length from the crossing. If because of the width of the crossing this is not practicable, the rail ends shall be welded to form continuous rail through the crossing.

Rails shall be double spiked to perfect line and track thoroughly and solidly tamped to uniform surface.

### Width of Crossing and Approaches

5. Crossings and approaches on the right-of-way shall be of sufficient width to permit traffic to move freely and avoid a bottleneck at the crossing.

The approaches on the right-of-way shall be improved with material identical with or equal to that of adjoining street pavement.

## (2) SPECIFICATIONS FOR THE CONSTRUCTION OF RAIL TYPE STREET CROSSINGS

### General

1. These specifications cover second-hand or scrap steel rails of lighter weight section than the running rails for use in the construction of rail type crossings. The specifications must be carried out in detail and with good workmanship.

### Track Structure, Width of Crossings and Approaches

2. Track structure, width of crossings and approaches shall be designed and constructed in accordance with the specifications covering this work for street crossings over railway tracks, both steam and electric.

### Materials and Installation

3. Intermediate and approach rails shall be of fair second-hand or good scrap quality. Curve-worn rail with excessive side head wear shall not be used. Care shall be taken to use rail showing approximately equal top head wear to provide level surface for the crossing. The variation in height of rails shall not exceed  $\frac{1}{8}$ -inch.

The space between running rails shall be filled with intermediate crossing rails, the number to be used to be determined by section of rail and requirement that distance between side of heads of adjacent rails shall not exceed four inches. The number of approach crossing rails to be used shall be determined by the same stipulation, with the additional requirement that distance from side of head of outside approach rail to edge of highway pavement shall not exceed four inches.

Creosoted hardwood shims not less than six inches in width and of proper thickness to bring tops of crossing rails level with tops of running rails shall be provided and securely nailed to each tie. Sawed cross-ties shall be used to provide full and even bearing for the shims.

All crossing rails shall be securely fastened with spikes at every third tie on each side of base of rail with spiking so staggered that rails will be spiked to each tie. Where dimensions between edges of adjacent rail bases do not permit such spiking, rail bases shall be notched to fit.

Crossing rails adjacent to running rails shall be so located that running rails may be renewed without necessity of removing crossing rails. It may be necessary to cut off a portion of the base of crossing rail to accomplish this, which shall be done where required.

Tie plate interference may prevent spiking down the edges of bases of crossing rails adjacent to the running rails. Where such spiking cannot be done, these crossing rails shall be fastened to the adjoining crossing rail with bolts not less than  $\frac{3}{4}$ -inch in diameter, spaced not less than six feet apart. Each such bolt shall be provided with pipe separator of proper length to make tight fit to prevent movement of crossing rail adjacent to running rail. If location of outside approach rail is too near the end of tie to be spiked down securely, then base of rail should be notched for proper spiking or rail bolted to adjacent crossing rail in manner just described.

All outside ends of crossing rails shall be bevelled not more than 45 degrees from the horizontal to prevent possible damage through being struck by dragging equipment.

For highway crossings in signal territory, the center rail shall be replaced with proper dimensioned creosoted timber for insulation.

The final elevation of top of rail shall be even with the highway pavement. If pavement beyond the track is of concrete a space of two inches shall be provided between ends of ties and the pavement in which shall be placed a bituminous felt strip two inches in thickness for the full depth and width of the pavement. If pavement is of construction other than concrete, a 4"  $\times$  18" creosoted timber header shall be placed on edge the full length of pavement to retain pavement, with same spacing and application of felt strip as for concrete pavement.

After the complete installation of the crossing rails, the openings on both sides of the running rails shall be filled to top of rail with poured bituminous filler. All other spaces between rails and between outside crossing rails and felt strip shall be filled to top of rail with the same material or other suitable material.

### (3) SPECIFICATIONS FOR THE CONSTRUCTION OF WOOD PLANK STREET CROSSINGS

#### General

1. These specifications cover the use of wood plank in the construction of this type crossing. The specifications must be carried out in detail and with good workmanship.

#### Track Structure, Width of Crossings and Approaches

2. Track structure, width of crossings and approaches shall be designed and constructed in accordance with the specifications covering this work for street crossings over railway tracks, both steam and electric.

#### Materials and Installation

3. It is recommended that creosoted planking and shims or furring strips shall be used. The accessibility of the various species of wood may determine the kind of timber and the kind of treatment, if any, that is most economical for use by an individual railway. This consideration should be the governing factor in the selection of the material to be used. When treated timbers are used the mill work required shall be done before treatment.

Crossing plank shall be of eight and ten-inch widths, not less than four inches thick, and shall be surfaced one side and one edge for uniform thickness and width. Commercial length planking of most economical lengths for the individual crossing shall be used. Length of planks shall be chosen to stagger joints so that no two adjacent planks shall have their intermediate ends on the same tie.

Shims not less than six inches in width and of proper thickness to bring tops of crossing planks level with top of running rails shall be provided and securely nailed to each tie. Sawed cross-ties shall be used to provide full and even bearing for the shims.

Planks shall be laid with  $\frac{1}{8}$ -inch to  $\frac{3}{8}$ -inch opening between edges. Each plank shall be securely spiked down at its ends and to every other tie, using two boat spikes driven diagonally to prevent heaving of the plank. Plank ends shall be bored for boat spikes to prevent splitting. For crossings where rail is between five inches and six inches in height, boat spikes  $\frac{1}{2}" \times 10"$  shall be used. Where rail is more than six inches in height boat spikes  $\frac{1}{2}" \times 11"$  shall be used.

Planks may be fastened down with lag screws instead of boat spikes. Where lag screws are used they shall be of same size as specified for boat spikes, but only one lag screw in each plank and in every other tie shall be required. Planks shall be bored for lag screws with hole  $\frac{1}{8}$ -inch larger diameter than that of lag screw, and shall be countersunk for washer and lag screw head.

The top of the plank crossing shall be even with the highway pavement. The edges of outside planks shall extend to and may project not more than one inch beyond ends of ties. If pavement beyond the track is of concrete, a space of one inch shall be provided between the edge of planking and the pavement. If pavement is of construction other than concrete a  $4" \times 18"$  creosoted timber header shall be placed on edge the full length of the pavement to retain same and a space of one inch shall be provided between the edge of planking and face of header.

Flangeway guards shall be installed in all important crossings; they shall be either dapped plank, old steel rail balled in, or of suitable patented type.

All outside ends of crossing planks and flangeway guards shall be bevelled not more than 45 degrees from the horizontal to prevent possible damage through being struck by dragging equipment.

#### (4) SPECIFICATIONS FOR THE CONSTRUCTION OF HIGHWAY CROSSINGS SURFACED WITH OIL PROCESSED GRAVEL

##### General

1. Oil processed surfacing shall consist of mixing No. 2 asphaltic road oil and a mineral aggregate at a mixing plant, hauling it to the crossing to be surfaced, and spreading, manipulating and compacting the mixture in accordance with these specifications.

##### Track Structure, Width of Crossings and Approaches

2. Track structure, width of crossings and approaches shall be designed and constructed in accordance with the specifications covering this work for street crossings over railway tracks.

##### Mineral Aggregate

3. The mineral aggregate shall be the product of a crushing and screening plant and shall be composed of hard durable fragments of rock and sand containing or having incorporated in it, limestone dust, iron oxide, or other binding material in such proportion that the whole will be of a homogeneous material complying with the grading and other requirements specified herein below. The material shall be uniformly graded from fine to coarse, and when tested by means of laboratory screens and sieves, shall meet the following requirements by weight:

Passing a screen having circular openings 1" in diameter—100 per cent.

Passing a screen having circular openings  $\frac{3}{4}$ " in diameter—85 per cent to 100 per cent.

Passing a No. 10 mesh sieve—45 per cent to 65 per cent.

Passing a No. 200 mesh sieve by washing—8 per cent to 15 per cent.

### Asphaltic Road Oil

4. (1) Asphaltic content not less than 80 per cent nor more than 90 per cent by weight of 100 per cent penetration asphalt, 100 per cent grains weight, 5 seconds, 77 degrees Fahr.

(2) Flash point—Open cup method—not lower than 270 degrees Fahr.

(3) Specific viscosity—Engler—at 122 degrees Fahrenheit—not less than 350.

(4) Water in sediment—not more than 2 per cent combined.

(5) Paraffin—not more than 2 per cent.

(6) Carbonaceous Flakes (Carbenes) basis per cent of 100 penetration asphalt, not more than 0.50 per cent. Tests on road oil are to conform to the most recent A.S.T.M. Standards.

### Mixing

5. The amount of this No. 2 oil shall be from 5 per cent to 8 per cent of the weight of the aggregate. Oil shall be from 150 degrees to 200 degrees Fahr. when added to the mix, and shall be added accurately by weight. Each batch of this material shall be mixed for at least ten seconds dry and then for a period of forty to fifty seconds after all ingredients are in the mix, and until a uniform mixture of unchanging appearance is obtained with all the particles of aggregate coated with oil.

The amount of moisture in the gravel or crushed rock at this time of the mixing shall not exceed 2 per cent of the weight of dry aggregate.

### Application

6. After track has been prepared in accordance with Section (2) of these specifications, a flangeway rail shall be applied. Such rail shall be laid on its edge so that its head shall fit snugly to the web of the running rail and securely fastened to prevent lateral movement. This may be done by placing a scrap angle bar spanning two ties against the base of the flangeway rail, at least four to each such 33-ft. rail, and spiking angle bars securely to each tie.

Ballast material shall then be brought up to a point two and one-half inches below the top of rail and shall be thoroughly tamped and rolled to insure a uniform, level and compact base for the oil processed gravel surfacing material.

If paving is done between tracks, five inches of sub-base consisting of specified rock or gravel, well rolled and compacted, shall be applied—the top of this sub-base to be two and one-half inches below the top of rail and finished grade of the highway.

Three inches of oil processed gravel shall now be spread over the prepared sub-base. It shall be well rolled until the mass has been fully compacted and thoroughly hand-tamped along the flangeway rail. During the process of rolling it is advisable to wipe the surface of the roller with kerosene to prevent oil processed gravel from sticking to it.

Three inches of oil processed material spread loose will compact about one-half inch and when completed, the surface of the finished crossing should be about level with the top of the running rails, but if slightly higher it should be left to be pounded down by traffic.

As soon as the oil processed gravel has been laid and compacted, traffic may be turned over the new surface immediately. If the finished surface is soft or sticky, cement shall be broomed over the entire area and a layer of fine dry sand spread over it, after which a heavy hand roller shall be used to imbed the sand in the paving.

Approximately a cubic yard of oil processed material shall be kept near the crossing so that any low spots that may be caused by vehicular traffic can be built up by application of a few shovels full of the material, as required.

Laying of oil processed gravel should preferably be done in warm, dry weather, and under no conditions during freezing weather. When gravel is put down on cold days it shall be applied in layers well compacted and metal, wood or concrete surfaces next to the layer of gravel shall be mopped with one coat of cut back asphalt.

If the oil processed material is laid as above, and properly and economically handled, one ton will cover about eight square yards of surface, after it has been compacted to a finished depth of two and one-half inches.

### Recommendation

Your Committee makes these recommendations:

(a) That the following specifications be adopted as recommended practice and published in the Manual:

(1) Specifications for preparation of track structure, width of crossing and approaches for construction of street crossings over railway tracks.

(2) Specifications for the construction of rail type street crossings.

(3) Specifications for the construction of wood plank street crossings.

(b) That Specification (4)—“Specifications for the construction of highway crossings surfaced with oil processed gravel,” be received as information.

(c) That this subject be continued for further study and preparation of specifications for other types of street crossings.

### Appendix D

#### (4) RELATIVE ECONOMY OF DIFFERENT TYPES OF HIGHWAY GRADE CROSSINGS

F. D. Batchellor, Chairman, Sub-Committee; F. J. Blickensderfer, John Carmichael, C. W. Charleson, H. M. Church, S. N. Crowe, C. A. Dayton, L. C. Frohman, A. G. Holt, W. B. Knight, A. E. Korsell, W. C. Swartout, A. H. Utter, V. R. Walling, R. F. Wood, W. L. Young.

The following types of crossings are generally in use:

Plank  
Bituminous  
Concrete  
Metal

To a lesser extent paved crossings of brick, granite and wood blocks are in use.

#### 1. Plank Crossings

(a) **UNTREATED PLANK.**—Until the advent of the automobile and trucks, with improved streets and highways, crossing plank was almost universally used for highway crossings. Since then, in some localities, it did not stand up under the traffic and substitutes began to appear. Today, particularly in the Western and Southern states, plank is still generally in use. It is also used in all states for minor crossings.

(b) **TREATED PLANK.**—These planks are being extensively used as they overcome, to some extent, the trouble which has been experienced on account of failure through decay. They have been used in the following way:

- (1) Built on same plan as untreated plank crossings.
- (2) Built same as above but with a protective covering for wearing surface of either rubber belting or bituminous material.
- (3) Built with the plank parallel with the center of the highway instead of parallel with the center of track.
- (4) Built in sections.

(c) **ASPHALT PLANK.**—These have been tried out but are still in the experimental stage.

A plank crossing, to make a satisfactory crossing, must be substantially built and securely fastened to the ties. It must be promptly and adequately repaired as needed.

If built and maintained as above, they make satisfactory highway crossings.

## 2. Bituminous Crossings

This type of crossing was one of the first substitutes for plank crossings and is extensively used in the Eastern and Middle Western states. There are several kinds, as follows: (a) bituminous material mixed with stone or gravel at crossings, (b) natural rock asphalt and (c) ready mixed bituminous material.

(a) **MIXED AT CROSSING.**—This type was one of the first bituminous crossings generally in use. The wearing surface is made by mixing the bitumen or emulsion, which is furnished in barrels, with rock or gravel. It requires considerable labor and more or less care in mixing the preparation.

(b) **NATURAL ROCK ASPHALT.**—The rock asphalt is a natural product and is shipped from the mine in cars ready for use and layer applied on top of stone or gravel for wearing surface.

(c) **READY MIXED.**—This type of bituminous crossing is one of the newest. It is readily handled as it is mixed at the plant and shipped in cars to the crossing. It is applied as a wearing surface by placing a layer on top of stone or gravel.

All bituminous crossings should be thoroughly rolled or tamped, preferably with a heavy power roller. They should be patched and rolled or tamped whenever depressions occur. For heavily traveled crossings they should have a metal flangeway, a rail on each side of the running rail, or one rail on inside of running rail. Heavy traffic on the highway improves this type of crossing.

Bituminous crossings, if built to the proper specifications and if properly maintained, make a satisfactory highway crossing.

## 3. Concrete Crossings

These types of crossings are used in cities and heavily traveled highways. The first concrete crossings were not altogether satisfactory as they chipped on the edges and in some instances cracked on account of heaving. In today's crossings these troubles have been overcome. There are the following types of concrete crossings:

(a) **SOLID CONCRETE.**—This type of crossing is not used to any great extent, due to the fact that the track cannot be readily repaired. However, where track does not have to be disturbed for a good many years, it makes a satisfactory crossing as it requires practically no maintenance.

(b) **CONCRETE PLANK.**—The earlier types of concrete crossings were concrete plank and were not altogether satisfactory. However, if properly constructed and securely fastened to the ties, they make a satisfactory crossing.

(c) **CONCRETE SLAB.**—This type of crossing is being used in cities and on main highways, particularly in the Eastern and Middle Western states. There are various designs of slabs and in some cases metal forms are provided and filled in with concrete at the crossing. When properly constructed and installed, this type of crossing is satisfactory.

#### 4. Metal Crossings

There are two types of metal crossings; rail and plate.

(a) **RAIL.**—This type of crossing has in scattered cases been in service for a good many years, especially on side tracks or unimportant branch lines. Lately, however, they are being more extensively used. The best types of this crossing are filled with concrete or bituminous material between the rails. These make a satisfactory crossing if properly installed. Provision should be made so that running rail can be renewed without tearing up crossing.

(b) **PLATE.**—Steel and iron plates, either fabricated, rolled or cast, are the latest type of crossing. Those which were first used were slippery and did not stand up under heavy loads. Those of today have overcome these objections by the use of projections on the plate and heavier design of the plate. They are used mostly in cities and heavily traveled highways. If of proper design and securely fastened to ties, these make a satisfactory crossing.

#### 5. Paved Crossings

This type of crossing has been used mostly to conform to the paving on the highway adjacent to it. There are not many of these crossings being put in today.

It will be noted that practically all of the crossings given above will make satisfactory crossings if properly constructed and maintained. As there are so many varying conditions at different crossings, we cannot recommend any of them as best for all crossings.

Particular attention is called to the fact that none of these crossings will give satisfactory results unless special attention is given in preparing the subgrade and track for the crossing. The track should be well drained, well ballasted, well tied, well tamped and lined and surfaced before crossing is put in.

Below is a statement giving some of the advantages and disadvantages of the various types:

| <i>Type of Crossing</i> | <i>Advantages</i>                                                                                                                                                                                   | <i>Disadvantages</i>                                                                                                                                        |
|-------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Plank (Wood)            | Can be installed without much trouble. Low first cost. Can be designed to fit any type Xing. Can be readily taken up to repair track.                                                               | High maintenance cost. Short life. Frequent maintenance. Liability of plank coming loose and being caught by dragging equipment or damaging tires on autos. |
| Bituminous              | Can be installed with track force. Can be used for surface for space between tracks. Low first cost. Can be designed to fit any type Xing. Improves with traffic on highway. Makes smooth crossing. | Gets rough unless patched from time to time. Liability of bitumen breaking next to running rail. Has to be dug up to repair track.                          |
| Concrete (Slab)         | Long life. Low maintenance cost. Makes smooth crossing.                                                                                                                                             | High first cost. Preferable to use sawed ties. Somewhat expensive to take up to repair track.                                                               |
| Concrete (Solid)        | Long life. Low maintenance cost.                                                                                                                                                                    | High first cost. Expensive to repair track.                                                                                                                 |

| <i>Type of Crossing</i> | <i>Advantages</i>                                                                     | <i>Disadvantages</i>                                                                                                                                                            |
|-------------------------|---------------------------------------------------------------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Rail                    | Long life. Low maintenance cost. Makes smooth crossing. Material generally available. | First cost high. Difficult to repair track.                                                                                                                                     |
| Plate                   | Long life. Makes smooth crossing.                                                     | First cost high. Preferable to use sawed ties. May be broken by derailed equipment. Brine drippings liable to affect life. Necessary to insulate in automatic signal territory. |

To find out which is the best and most economical type for any particular crossing, the following should be determined:

- (1) Kind of track structure.
- (2) Number of times crossing has to be disturbed to repair track.
- (3) Availability and cost of crossing material.
- (4) Amount of travel on highway.
- (5) Amount of travel on railroad.
- (6) First cost of crossing.
- (7) Life of crossing.
- (8) Cost of maintenance per year.
- (9) Kind of pavement each side of crossing.
- (10) Weather conditions.
- (11) Traffic reasons.

After having determined the above, we suggest the following formula be used to determine the most economical type of crossing.

$$\frac{a}{b} \text{ plus } c \text{ plus } d \text{ equals } e$$

$a$  = First cost of crossing per square foot.

$b$  = Estimated life in years.

$c$  = Interest on first cost per square foot.

$d$  = Cost of maintenance per square foot per year.

$e$  = Cost per square foot of crossing per year of estimated life.

To determine the cost per running foot of track, multiply the cost per square foot by  $8\frac{1}{2}$  or whatever width is required.

One of the principal items in using this formula is the estimated life of the crossing. Unfortunately, information as to this is not available and if it were, it would not apply to all crossings, unless the conditions were similar at each crossing.

The statement below is compiled from information furnished by different railroads in different states and is given only as information as to what they estimate will be the life of a crossing where conditions are similar to the crossing reported.

The summary of this statement, given at the bottom, may or may not be of value, as showing the comparative average estimated life of the various types of crossings, depending on whether or not conditions at the crossings are similar.

| <i>Type of Crossing</i> | <i>Location</i>   |              | <i>Life in Years</i> |                  |
|-------------------------|-------------------|--------------|----------------------|------------------|
|                         | <i>Railroad</i>   | <i>State</i> | <i>To Date</i>       | <i>Estimated</i> |
| Untreated Plank         | C. B. & Q. Ry.    | Neb.         | ..                   | 5                |
| " "                     | B. & O. R. R.     | Ohio         | 6                    | 6                |
| " "                     | C. R. I. & P. Ry. | Iowa         | 1                    | 5                |
| " "                     | " "               | Ark.         | 3                    | 5                |
| " "                     | E. J. & E. Ry.    | Ind.         | 4                    | 5                |

| Type of Crossing    | Railroad              | Location | State  | Life in Years |           |
|---------------------|-----------------------|----------|--------|---------------|-----------|
|                     |                       |          |        | To Date       | Estimated |
| Treated Plank       | C. & O. Ry.           |          | Ky.    | 5             | 6         |
| " "                 | Mo. Pac.              |          | Texas  | 3             | 15        |
| " "                 | K. C. Sou.            |          | Kan.   | 11            | 18        |
| " "                 | E. J. & E. Ry.        |          | Ill.   | 1             | 8         |
| " "                 | C. & O. Ry.           |          | Ohio   | .5            | 6         |
| Asphalt Plank       | N. & W. R. R.         |          | Ohio   | 3             | 3         |

## (5) PROPER VERTICAL CURVES ON HIGHWAYS FOR GRADE SEPARATION PROJECTS

E. R. Lewis, Chairman, Sub-Committee; John Carmichael, C. W. Charleson, S. N. Crowe, R. C. Gowdy, A. G. Holt, A. E. Korsell, W. S. Lacher, T. M. Pittman, L. J. Riegler, H. M. Shepard, F. P. Sisson, V. R. Walling, R. F. Wood, A. M. Zabriskie.

## Definition

**HIGHWAY VERTICAL CURVE.**—An easement curve designed primarily to afford safe vision and/or enough gradual change in direction to minimize angular shock.

Railroad and highway vertical curves are dissimilar because of the essential difference between railroad and highway traffic. The railroad vertical curve is designed to

counteract the tendency of the cars in a train to run together in sags and to pull apart on summits. The highway vertical curve is designed to provide safe vision for drivers of single, or at most three coupled, vehicles of comparatively short wheel base; and/or gradual change in direction while passing from one grade to another. The ends of the vertical curves farthest from the crossing of railroad and highway involved, mark the physical limits of the grade separation project. Being grade separation items, all this vertical curvature is subject to joint consideration and agreement.

Practice covering highway vision curves is fairly well established. A common minimum of safe vision required by many State authorities is 500 feet for Class I highways, the line of sight being five feet above paving surface. The vertical curve length depends on the algebraic difference of intersecting gradients, on permissible speed and on the vision required. Unlighted highways require sag curves flat enough to permit automobile head lamp rays to intercept the surface at a distance that provides sufficient length of illuminated roadway. It is apparent that "safe vision" is required essentially to protect against careless driving. Few collisions would occur if all vehicles remained in the proper lanes of travel and if stationary obstructions were kept clear of the roadway. Head-on collisions can only occur when one or both vehicles are trespassing. Tail end collisions result from reckless driving or from disregard or absence of signals. Since the 500-ft. minimum vision applies to the practically unlimited speeds of the country highway, the speed restrictions, lane markings, superior signal protection, lighting and close policing of city streets, permit the use of much shorter vertical curves with reasonable safety in cities.

Many grade separations also provide separated roadways for one way traffic. Curves for vision in such cases are not so vital. The parabolic vertical curve is the design in general use. The 500-ft. vision is by no means rigidly observed even on Class I highways in rural districts, for it is not to be supposed that in any country of wide expanse, diversified topography and gradual settlement any single standard would suffice. The class of road, the density of traffic and many local conditions govern vertical curve selection. Many paved highways follow closely the sharp grade changes and undulations of the original surface in mountainous or hilly terrain, especially in the older settled districts where summits remain sharp, while sags have been modified for drainage rather than for rideability. The complications of horizontal curves with their vision obstacles of woods, excavation slopes, buildings, etc., further influence selection of vertical curves. In order that the approach to a horizontal curve be not hidden, the vertical curve advisedly is kept wholly within the horizontal curve limits.

The sag curve, where vision is unobstructed, may be limited to mitigating angular shock. Inasmuch as an algebraic difference of five per cent of gradient involves the very flat angle of two degrees, fifty-two minutes, a vertical curve less than 100 feet long will serve such a grade change at high speeds. Sag curves heretofore have received comparatively little study, with the result that long sweeps are installed commonly for appearance sake and for little other reason. Study of sag curves not involving vision should be based on location, permissible speed and angle of intersecting grades.

Good practice in highway design of grade separations excludes horizontal curves from the structure and approach roads wherever possible. Obstructions to view are carefully avoided or eliminated. City streets usually are straight and require only change in elevations. Streets intersecting approach roads are eliminated wherever feasible. Thus the grade separation project becomes a specialty in highway design so far as vertical curvature is concerned. Whether the highway be elevated or depressed for separation purposes, the location of the point of intersection of grade lines at or near the point of crossing of the center lines of railroad and highway is usually desirable and

economical in conserving space and minimizing expense. Length of structure, underground pipe lines, etc., frequently prevent central curve location. Where a long viaduct or subway separates the highway from multiple tracks as in a railroad yard, the horizontal or drainage grade connected with vertical curves at the bottom of each approach becomes necessary. Drainage must be cared for in connection with any vertical curvature design.

Sag curves of 20 to 50-ft. length are common in grade separations in most large cities. No discomfort is felt in traveling these curves at speeds restricted to 25 to 40 miles per hour, usual maxima permitted in cities. Sight distances of 250 to 300 feet are admitted safe for these speeds. In many cases the vision curve length does not exceed 100 feet or even less. Roadway markings, policing, etc., take the place of extravagant vertical curves. Reason, rather than rule, should govern selection everywhere. The location and design of highways at grade separations should reflect a balance between maximum safety and comfort to the road user (which involves grades, alinement and horizontal and vertical sight distance) and a reasonable expenditure of funds.

Design of vertical curvature should be made to fit the conditions, eliminating any tendency to treat all sag curves in terms of vision curve lengths, to treat city grade separation vertical curves in terms of the unrestricted sweep and speeds of the open road. There is a balance of safety and economy attainable in every case which, if fairly and intelligently considered in the light of a weighted average of all the factors involved, invariably determines vertical curve lengths of greatest advantage. Beyond the limits of safety and utility, vertical curvature required should be the sole responsibility of the initiating party. Minima of 10 feet length for each 1 per cent of change in gradient for vertical curves in urban grade separation projects; and 15 feet for each 1 per cent of change in gradient for highways outside of cities are suggested. Sight distance curves merit special designs.

### Recommendation

It is recommended that depression or elevation of highways required for separation from railroad grades be effected with the minimum of vertical curvature required for safety and utility.

It is further recommended that the foregoing be approved and published in the Manual.

### Appendix F

#### (6) INVESTIGATE THE USE AND REPORT ON THE MERITS AND ECONOMY OF THE "STOP AND GO" TYPE OF SIGNAL WITH RED AND GREEN ILLUMINATED ASPECTS, AS A PROTECTIVE DEVICE AT HIGHWAY-RAILWAY GRADE CROSSINGS, UNDER USUAL CONDITIONS AND SPECIAL CONDITIONS

R. C. Gowdy, Chairman, Sub-Committee; Bernard Blum, F. J. Blickensderfer, H. E. Brink, A. T. Danver, A. R. Dewees, G. N. Edmondson, C. F. Edwards, H. L. Engelhardt, P. M. Gault, W. S. Lacher, G. P. Palmer, W. C. Pinschmidt, H. M. Shepard, W. C. Swartout, A. H. Utter, Leroy Wyant.

The "Stop and Go" type of signal has no outstanding advantages over "Wigwag" or "Flashing Light" types, and it has some serious disadvantages. Their average cost of installation is about the same as that of "Flashing Light" and "Wigwag" signals under

similar conditions, but the cost of operating them is of necessity greater because of the fact that their lamps burn continuously throughout the day and night, requiring a greater consumption of current and more frequent renewal of lamps. "Flashing Light" and "Wigwag" signals consume current and operate only while trains are passing. It is claimed that "Stop and Go" signals are identical with the usual type of highway signals, but such is not the case. Highway traffic signals indicate "Go" only when the "Stop" signals are displayed against conflicting traffic, but "Stop and Go" signals at railway crossings do not display any "Stop" signal toward trains, and in some instances the signal would not be visible from approaching trains. Ordinarily at street intersections traffic signals are displayed in four directions, but at railway crossing signals would be displayed in only two directions. Highway traffic signals stop traffic on one highway or street, permitting it to go on the other, alternating the condition, but at railway crossings trains have the right-of-way and when railroad movements are not frequent the green light might be displayed for a considerable length of time without alternating with the red light. A long display of either red or green light without change or movement is liable to cause motorists to disregard its importance.

At crossings where main tracks only are protected, but where sidings are not, and trainmen are required to flag across a street or highway, the display of a green light while a trainman was attempting to stop traffic on the highway with a flag or lamp would result in confusion, unless auxiliary manual control is provided. A green signal is generally recognized as a positive command to go, and any conflict of signals with it by hand or otherwise should be avoided. A "Flashing Light" or "Wigwag" signal calls attention to the crossing, but it does not conflict with other signals being displayed, and does not relieve motorists of their legal obligation to see that no train is approaching, and that the crossing is clear. At street and highway intersections it is noticeable that vehicles approaching green signals increase their speed in an effort to cross before the light changes. A green light at a railway crossing is an invitation to drivers to cross as quickly as possible, and is directly opposed to efforts of states and municipalities to slow down traffic at such crossings.

A steady red light is not as noticeable as a moving or flashing light of the same color, and there is less chance of all lights in a "Flashing Light" signal burning out than there is of the single red light in the "Stop and Go" type.

It is argued that "Stop and Go" signals, due to their resemblance to the usual traffic lights, would be observed by the public, but this is doubtful. It is a common occurrence for drivers to ignore traffic lights unless such lights are under police supervision, and at railroad crossings in the open country without police supervision, there would probably be a general disregard of them.

The American Railway Association, through its committees, has been working for a number of years for standardization throughout the country in grade crossing protection, and has been successful in procuring the adoption of "Wigwag" or "Flashing Light" types of signals at a great many crossings. To now recede from its position and recommendations to states and municipalities, and to call attention to the "Stop and Go" type of signal, would seriously retard progress already made.

There is at the present time no general demand on the part of the public or state or municipal authorities for the installation and use of "Stop and Go" signals, and there have been few if any complaints of the "Flashing Light" or "Wigwag" types. These latter types are generally known and recognized throughout the country as indicating railway crossings, and the number of types of signals for that purpose should be limited to as few as possible, instead of introducing new types which have been developed for crossings and intersections dissimilar to railway crossings.

In some special instances "Stop and Go" signals may properly be interconnected with railroad signals, but such cases are rare and each should be considered on its own merits, having in mind the particular conditions governing each installation.

### Conclusion

"Stop and Go" signals should not be used for the protection of railroad-highway grade crossings where they are operated exclusively by the passage of trains, and their use should be confined to special locations where their observance can be enforced by police power.

### Recommendation

It is recommended that the conclusion be approved and that the Joint Committee on Grade Crossing Protection, A.R.A., be notified of such conclusion.

## REPORT OF COMMITTEE XI—RECORDS AND ACCOUNTS

### *To the American Railway Engineering Association:*

Your Committee respectfully presents herewith reports covering the following subjects:

#### **Group A—Miscellaneous**

- (1) Revision of Manual (Appendix A).
- (2) Bibliography on subjects pertaining to records and accounts (Appendix B).

#### **Group B—General Railway Engineering Reports and Records**

- (1) Office and drafting room practices (Appendix C).
- (2) Joint facility records: (Appendix D)
  - (a) Appraisal methods and records for keeping up to date.
  - (b) Maintenance and operation reports and records.
  - (c) Effect of depreciation accounting.
- (3) Bridge inspection report forms (Appendix E).

#### **Group C—Maintenance of Way Reports and Records**

- (1) Statistical requirements of operating, accounting and other departments with respect to maintenance of way and structures, collaborating with appropriate committees (Appendix F).
- (3) Forms used by railway water service departments (Appendix G).

#### **Group E—Valuation**

- (1) Methods and forms for gathering the data for keeping up to date the valuation and other records of the property of railways with respect to: (Appendix H)
  - (a) Changes made necessary by government regulations.
  - (b) Simplicity and practicability of use.
- (2) Methods used in recapture proceedings (Appendix I).

#### **Group F—Accounting Practices Affecting Railway Engineering**

- (2) Developments under I.C.C. Order No. 15100—Depreciation Charges of Steam Railway Companies (Appendix J).
- (3) Methods for avoiding duplication of effort and for simplifying and co-ordinating work under the requirements of the I.C.C. (Appendix K).

### Action Recommended

- (1) That the report under Appendix A be approved as recommended practice and printed in the Manual.
  - (2) That Appendix B be received as information and the subject continued.
  - (3) That the report under Appendix C be approved as recommended practice and printed in the Manual, and the subject continued.
  - (4) That Appendix D be received as information and the subject discontinued.
  - (5) That the report under Appendix E be approved as recommended practice and printed in the Manual, and the subject discontinued.
  - (6) That Appendix F be received as information and the subject continued.
  - (7) That the report under Appendix G be approved as recommended practice and printed in the Manual and the subject discontinued.
  - (8) That Appendix H be accepted as information and the subject continued.
  - (9) That Appendix I be accepted as information and the subject discontinued.
  - (10) That Appendix J be accepted as information and the subject continued.
  - (11) That Appendix K be accepted as information and the subject continued.
- Progress is reported on subjects C-2, F-1, F-4.

Respectfully submitted,

THE COMMITTEE ON RECORDS AND ACCOUNTS,

C. C. HAIRE, *Chairman*.

### Appendix A

#### (A-1) REVISION OF MANUAL

D. W. Smith, Chairman, Sub-Committee; E. S. Butler, W. L. Foster, J. H. Hande, A. T. Hopkins, P. R. Leete, W. M. Ludolph, E. W. Metcalf.

The Committee recommends for adoption by the Association the following revisions:

#### *Present Form*

#### *Proposed Form*

Pages 726 and 727, paragraphs 6 and 7  
near bottom of page.

- (e) Equipment Completion Report.  
Form 1118.

#### SPECIFICATIONS FOR FORM 1118.

Form as shown. Size 11 × 17 inches.

All lines and printing black.

#### INSTRUCTIONS FOR USE OF FORM 1118.

A report must be prepared on this form for each equipment project by the designated officer, as soon after completion as possible, listing and describing the units of equipment affected and giving careful description of the changes made and listing the units involved, both added and retired, with the cost of each. If a project involves changes in a number of units completed in more than one six months' period

Omit

*Present Form*

a progress report should be made covering the changes completed in each six months' period. When the whole project is finished a final report should be prepared covering all the changes made under A.F.E., which will be a summary of all the semi-annual progress reports.

*Proposed Form*

Omit

*Present Form**Proposed Form*

## 7. LABOR AND GENERAL FORMS.

## (a) Time Roll. Form 1119.

## SPECIFICATIONS FOR FORM 1119.

Form as shown. Size of book,  $5\frac{1}{2} \times 8\frac{1}{2}$  inches. Cover to be of three-ply manila paper, book proper to be on yellow paper; printing to be in black. Book to contain 12 pages. Form shown is reduced size.

Page 758, *paragraph 4.*

Carriers are constantly striving to get the maximum worth of the maintenance dollar. They should be able to show that their expenses are efficiently and economically handled as a matter of sound business practice, but since the passage of the Transportation Act, 1920, it is essential that this information be readily available in handling matters with the Government pertaining to the recapture clause of this Act.

Carriers are constantly striving to get the maximum worth of the maintenance dollar. They should be able to show that their expenses are efficiently and economically handled as a matter of sound business practice.

## Appendix B

## (A-2) BIBLIOGRAPHY ON SUBJECTS PERTAINING TO RECORDS AND ACCOUNTS

A. P. Weymouth, Chairman, Sub-Committee; E. V. Braden, C. K. Smith, H. J. Stroebel, D. C. Teal, W. H. Woodbury.

The method followed in compiling this bibliography for the current year is similar to that used in previous years. Each member was assigned certain periodicals to review and report on important articles, and any new books of interest.

The following is respectfully submitted as a bibliography review covering the period from November, 1932, to October, 1933, inclusive.

## BIBLIOGRAPHY

## I—Books

The Coordination and Development of Transport; Final Report by the British Royal Commission presented December, 1930. Henry Sotheran, Ltd., London, England.

Public Utility Regulation. By Wm. Mosher and Finla G. Crawford. Harper and Bros., June, 1933.

Railway Operations for 1932. Special Series No. 59, Bureau of Railway Economics, May, 1933.

Electrification of Steam Railways. Sixth Report of Electrification. Committee of National Electric Light Assoc. (Publication 247), May, 1933.

Railroads of Brazil, public and private operation of railways. By Julian S. Duncan, Columbia University Press, Jan., 1933.

Rate making under present economic conditions. By N. T. Veach, Jr., American Water Works Assoc. Journal, Vol. 25, No. 3, March, 1933.

Value Theory and Business Cycles. By H. L. McCracken, Falcon Press, N. Y., Sept., 1933.

The American Railroad in Laboratory, American Railway Assoc., 1933.

## II—Periodicals

### (a) GENERAL RAILWAY SITUATION

Railways propose legislative program. Railway Age, December 10, 1932, p. 859.

National Transportation Committee makes report, Railway Age, February 18, 1933, p. 247.

Reorganization law in effect. Railway Age, March 11, 1933, p. 362.

New transportation policies proposed by the National Chamber of Commerce, including changes in railroad regulation. Nation's Business, February, 1933, p. 50.

The railroads' need for a new deal, article by A. B. Barber in Nation's Business, June, 1933, p. 40.

Rail and motor rivals getting together. Comments on and summary of the report of the joint committee of railway and highway users. Literary Digest, Feb. 18, 1933, p. 40.

Congress passes Railroad Bill, the Emergency Railroad Transportation Act 1933, providing for a Federal Coordinator, revision of the rule of rate-making, repeal of recapture provisions, and reduction in valuation work. Railway Age, June 17, 1933, p. 865.

Rail relief by Co-ordination, introducing Mr. Eastman to his new job as Federal Coordinator of Railroads, Literary Digest, June 17, 1933, p. 6.

Speeding up the Railroads. The Federal Coordinator seeks to unify the National Transportation System. Article by Lawrence Sullivan, Literary Digest, October 14, 1933, p. 5.

### (b) VALUATION

Interstate Commerce Commission plans to make valuation records current. Statement of Commissioner Lewis before annual convention of National Assoc. R. R. and Pub. Utility Commissioners, Railway Age, November 26, 1932, p. 740.

The Interstate Commerce Commission on December 17, 1932, issued six orders pertaining to the modification, suspension and cancellation of valuation orders. Railway Age, December 31, 1932, p. 991.

A decision of the Supreme Court, rendered May 8, 1933, in the case of Los Angeles Gas & Electric Corp. vs. R.R. Commission of the State of California discussed at some length principles of valuation and methods for determination of rate base. Case was referred back to District Court for review and report.

### (c) ACCOUNTING

The Supreme Court of the U. S., in a decision rendered November 7, 1932, sustained the validity of an order of the I.C.C. requiring the N. & W. Ry. to carry certain coal mine properties on its books as "Miscellaneous Physical Property" instead of transferring them to the Road & Equipment account. Ry. Age, Nov. 12, 1932, p. 687.

I.C.C. ruling in connection with rebuilding of freight cars, Accounting for same as additions. Traffic World, Jan. 14, 1933, p. 58.

Improved car accounting and statistics at lower costs is reported by Boston & Maine R.R. with punch card equipment. Railway Age, April 15, 1933, p. 548.

B. & O. R.R. changes depreciation basis for equipment from a "service mile" basis to a percentage of ledger value, in order to conform to a criticism of the I.C.C. Railway Age September 16, 1933, p. 417.

Coordinator Eastman announced the appointment of a committee to investigate the subject of railroad cost-finding and the possibility of introducing new accounting and statistical methods. Railway Age, September 23, 1933, p. 446.

**(d) FOREIGN**

Report of Special Committee Appointed to Investigate and Report on Certain Specific Questions Relating to The Capital Indebtedness of the Victorian Railways, 1933. H. J. Green, Government Printer, Melbourne, Australia.

**Appendix C****(B-1) DRAWING AND DRAFTING ROOM PRACTICE**

D. L. Avery, Chairman, Sub-Committee; A. M. Blanchard, R. R. L. Bullard, V. H. Doyle, W. L. Foster, C. A. Knowles, W. M. Ludolph, D. W. Smith, D. C. Teal, G. R. Walsh, A. P. Weymouth.

The Committee devoted most of its time during the year preparing a pamphlet covering Electrical and Signal Symbols. At the request of Committees X—Signals and Interlocking and XVIII—Electricity, it was decided to discontinue work pertaining to their symbols.

Last year's report of the Committee has been revised to include constructive suggestions and additions offered during the year.

**Action Recommended**

It is recommended that the report be approved for publication in the Manual.

**Appendix D****(B-2) JOINT FACILITY RECORDS**

- (a) Appraisal methods and records for keeping up-to-date.**
- (b) Maintenance and operation reports and records.**
- (c) Effect of depreciation accounting.**

B. A. Bertenshaw, Chairman, Sub-Committee; Anton Anderson, D. L. Avery, E. V. Braden, E. S. Butler, James Erskine, W. L. Foster, C. C. Haire, J. H. Hande, G. R. Walsh.

**General**

It is common practice where facilities are owned by one railroad and jointly used by one or more other railroads to cover the use, maintenance and operation of the jointly used facilities by formal contract or agreement. There is at present a trend toward the elimination of duplicate facilities and the unification of small differently owned properties into a larger operating unit, which will largely increase the number of Joint Facility Agreements and make desirable any methods and forms which will enable the railroads to easily maintain records of changes in the jointly used property and to assist in their performance according to the agreement.

**(a) Appraisal Methods and Records for Keeping Up-to-Date**

In Joint Facility contracts the using company usually agrees to pay to the owning company a rental for the use of the joint facilities. This rental is usually a specific per cent per annum on a rental base or sum of money agreed upon at the time the agreement is executed. The determination of this rental base is in most cases subject to prolonged negotiation, and various methods and records are used to assist in fixing the sum finally agreed upon. The Committee has made a study of the different ways of arriving at the rental base, and found the following have been most commonly used:

1. Appraised value agreed to by interested parties.
2. Ledger value or original cost.
3. Estimated original cost.
4. Cost of reproduction.
5. I.C.C. Valuation (Tentative or Final).

There are so many modifying factors to be taken into consideration that no ironclad rule or formula for arriving at the rental base is practical. Some of the factors to be considered in arriving at a rental base are:

1. Age of property.
2. Condition as regards maintenance and depreciation.
3. Fluctuating costs affecting value.
4. Local conditions.
5. Different capacity requirements of interested parties.

Regardless of which method is used in deriving the figures to be used in the negotiations, the basis should be an inventory of the property under consideration. This inventory may be readily obtained for property in existence on Date of Valuation of the owner by taking the field inventory of the Bureau of Valuation and adjusting it for subsequent changes from an inspection of the property and Valuation Order No. 3 records; for property constructed since Valuation Date the inventory is easily obtained from Construction and Valuation Order No. 3 records.

If the ledger value or original cost is known, and it is decided to use this as a basis for negotiation, there remains only the application of original costs to the inventory. If some other basis is to be used, then unit prices as of some selected period or level may be applied to the inventory (for this purpose the most readily available are those

used by the Bureau of Valuation for the period 1910-1914) and the necessary adjustments made by use of index numbers; further adjustments may then be made for depreciation or other modifying factors.

The rental base as finally agreed upon is often neither the exact ledger value nor the sum developed by the owner prior to the negotiations as representing the value of the property. In such cases each unit or item of the inventory should be apportioned its pro rata share of the rental base.

The rental base having been determined, provision must be made to keep this base up to date, due to changes in the property from time to time. Different methods have been used for this purpose, the most common of which are:

1. By adding the net expenditures chargeable to Capital Account as reflected in the accounting records.
2. By maintaining a detail of the original appraisal with additions and retirements, and retiring therefrom items that can be identified, or equitably estimated portions thereof, at the amount included in such detail for the property retired.
3. In case of retirements, retire from the rental base the percentage which the property retired bears to the total.

As stated above, the rental base is seldom the same amount as that carried in the accounting records of the owning company for the property jointly used, so that if, when any of the property is retired, the rental base is adjusted by deducting the same amount as is retired from the owner's books, an improper amount may be deducted, and over a period of time, with frequent changes in the property, the rental base will become considerably distorted. Furthermore, where property is added, the owning company usually adds more to the rental base in the way of percentages for overhead, supervision, etc., than it adds to its own capital structure; this increase should also be deducted from the rental base for corresponding retirements.

In fairness to both owner and user, records should be kept that will show

1. That portion of the rental base assignable to each unit of property as of the date of the agreement.
2. Additions—Amount lodged in the accounting records of owner and amount added to rental base.
3. Retirements—Amount retired from books of owner and amount retired from rental base.

The nature and extent of jointly used properties, carrier organization and method of handling joint facility bills vary to such an extent as to make it impractical to design a form for uniform use. The property may consist of anything from a single structure, sidetrack, or piece of single main track without appurtenances to a long stretch of multiple main track road with all appurtenances. The Committee presents as Exhibit A a form 11" × 17", with columnar headings under which to record pertinent information for keeping the rental base up-to-date.

In column headed "Item" is to be listed the items included in the property as of the date of the agreement, leaving space for subsequent addition of similar items. The extent of the jointly used property, and consequently the bulk of the record, will determine the amount of detail to be recorded. For example, if the jointly used property is relatively small and of a single nature, such as a single main track or a few yard and sidetracks, or a single structure, a complete detail of ties, rail, track fastenings, concrete, structural steel, etc., may be listed, but if the property is extensive and of a complex nature it may be desirable to make the items listed composite in nature, such as a complete structure, a complete side or yard track, water station, etc.

After the items have been listed in accordance with the requirements, the proper unit designation is to be recorded in the next column. The following two columns are

| --- | Turnout to Schlosser Bros Track at Tenth St.                                     | Road A: 100%                           | N & S R.R.   | Road A: 100%                                                    | N & S R.R.   | Road A: 100%                                                | 832                                |

NOTE 1-Road "B" pays \$16,600 per year in equal monthly payments, 1/2 each to N & S R.R. and Road A for interest, rental, maintenance, depreciation, taxes and insurance.

NOTE 2-N & S R.R. maintains all pipe connections and dwarf signals between Tenth and Eleventh Sts and bills Road A 50%.

NOTE 3-N & S R.R. owns all pipe connections and dwarf signals between Tenth and Eleventh Sts, and bills Road A and Road B 1/5 each.

NOTE 4-N & S R.R. owns switches of X over #71 in Eastward Main and X over #872 in Track #123-Road B billed 1/5 and Road A not billed-Road A owns switches of X over #871 and #872 in Westward Main N & S R.R. not billed

NOTE 5-City bills N & S R.R. and Road A 15% each for expense of Street Lighting at 2nd St. 5' 6" 7' 8" and 9' Sts. Each Road then bills Road B for 1/5 of its 15%.

NOTE 6-Agreement must be reached in advance as to performance of work and division of expense. See Chief Engineer's Letter of 10-1-31.

SHEET 2 OF 2

placed under a general heading of "Rental Base". In column headed "Number Units" is to be recorded the number of designated units included in the rental base, and in the next column, headed "Amount", the pro rata share of the rental base assignable to these units.

Provision is made on this form for three separate changes affecting any item or set of items. Continuation sheets may be used for additional changes. For each change, space is provided at the top of the general division for recording general information, as A.F.E. No., date of change, and a brief general description. There are five columns in which specific information regarding each change is to be shown. The first of these columns is headed "Number Units" and each regular horizontal space on the form has been divided into two spaces in this column. In the upper space will be recorded the number of units added, while in the lower space will be the number of units retired. In the next two columns are to be shown the amounts added in the accounting records and to the rental base respectively, while in the last two columns are shown the amounts deducted due to retirements, first as lodged in the accounting records and next as affecting the rental base. In the case of betterments, due to the fact that the amounts in the books and in the rental base are in effect changed only by the net additional cost of the betterment, no entry will be made in the "retired" columns; only the net additional cost will be shown in the "added" columns. In extensive jointly used properties, or those made up of a large number of small items where it is necessary to adjust the rental base at frequent intervals, it may be desirable to assemble from Exhibit A the amount of the changes in the various items or units and carry the net total change in amount on a separate sheet, but no special form would be necessary in such a case.

#### **(b) Maintenance and Operation Reports and Records**

In addition to the usual maintenance and operating records maintained by the owning company in connection with bills rendered against the user, there is a need for some record to be placed in the hands of those responsible for the maintenance and operation of the joint facilities, in order that reports may be originated to bill all expense in accordance with the agreement. This need is emphasized where there are frequent changes in personnel and new employees must become familiar with conditions that have grown up over a number of years, and where various departments handle charges that are finally assembled into a single bill against the user.

Exhibits B and C have been designed to illustrate records setting out the ownership, maintenance and operation of a typical joint facility. These exhibits are each 11"  $\times$  17" in size, Exhibit B being a plan not drawn to scale, showing the facilities jointly used by means of lines and symbols; the facilities are designated according to ownership, use, maintenance and operation. Exhibit C is a schedule of these same facilities, in which is given a brief description of the various properties according to ownership, use, etc., showing who is in charge of the maintenance and operation, together with the division of the expense of same. There is also a list of contracts and agreements that are applicable to the facilities.

Wherever possible, the schedule of facilities should be placed on the same sheet as the plan, the governing feature being the size of the sheet required to do this. It should not be large enough to make it unwieldy or cumbersome for use in the field. No particular size is recommended, as each road should make a study of the extent of the joint facilities to be taken care of and then adopt a suitable size (multiples of 11"  $\times$  17" are recommended), as it is very desirable that all be finally placed on sheets that may be conveniently bound in book form.

A study was made in an effort to determine what method is preferable for distinguishing different combinations of ownerships, use, etc. Where the facilities are not

extensive and the layout simple, these various conditions may be represented by using different weights of lines or solid and dashed lines for tracks; other facilities may be numbered or lettered, or a combination of numbers and letters used, and in some instances the schedule of facilities itself may be all that is necessary. But it is the opinion of the Committee that in complicated territory where several distinctions are necessary in the track layout and where the jointly used properties consist of a number of small scattered units such as signals, watchmen's shanties, crossing gates and bells, the additional expense of showing these in different colors is more than compensated for by the ease with which the print may be read and the different facilities located or identified. This is especially desirable in case the plans are placed in the hands of those directly responsible for maintenance and operation, such as supervisors and foremen, for use in the field.

Provision should of course be made to keep these charts up-to-date, else their value will be very largely destroyed. This should be a simple matter if placed in charge of someone who would be notified of all physical changes as well as changes in maintenance and operation. In addition to correcting the subject-matter on each of the charts, the date and nature of the revision should be indicated in a space provided for that purpose, near the title.

### **(c) Effect of Depreciation Accounting**

For many years Federal and certain State regulatory bodies have urged that the railroads adopt a system of depreciation and amortization accounting for their property. This has manifested itself by the Order issued by the Interstate Commerce Commission under Docket No. 15100, Depreciation Charges for Steam Railroad Companies, which, after being made a mandatory order, was suspended.

It has been noted, however, that a few railroads are preparing their contracts in connection with new joint facility agreements so as to anticipate that depreciation accounting will be a requirement. Following are several principal features covering depreciation that are included in certain modern contracts:

1. Provision to include as an operating expense an amount representing depreciation, if and when the I.C.C., or public bodies having jurisdiction in the premises, shall require the accrual thereof.
2. The provision to reduce the capital sum upon which interest is paid as rental by the aggregate amount of any depreciation accruals (less the aggregate amount of charges for retirements).
3. Provisions are made for amortizing the residual capital sum upon which depreciation has not been accrued, in the event the carrier withdraws from the use of the joint facility or any part thereof in accordance with period used as compared to total estimated life.
4. Provisions are made for the future payment periodically, such as monthly, for the proportion of retirement values upon which depreciation has not been accrued, in the event of a large sized retirement.

### **Conclusions**

The Committee is of the opinion that if Joint Facility contracts are made to state specifically how the rental base is to be adjusted, both for additions and retirements, and if records are maintained similar to those outlined above, then not only will billing between roads be less troublesome, but the rendering and checking of joint facility bills will be very much simplified.

The Committee recommends that the report be accepted as information, and the subject discontinued.

**Appendix E****(B-3) BRIDGE INSPECTION REPORT FORMS**

C. C. Haire, Chairman, Sub-Committee; A. T. Hopkins, F. C. Kane, P. R. Leete, D. W. Smith, G. R. Walsh.

Several progress reports have been made by the Committee during the past several years, but there has not been an unanimity of opinion with the other collaborating committees. This year the forms have been designed so that the five committees are now in accord. There are now included in the Manual two forms for the inspection of bridges: Form 1110, on page 716, for the purpose of general bridge inspection, and Form 1111, on page 718, for the purpose of special inspection. The Manual also contains, pages 847 to 849, inclusive, rules for the inspection of bridges. It is proposed by the Committee that these two forms be superseded by three forms numbered 1110 Rev., 1110-A and 1110-B.

The Committee has given consideration to the practice of many roads, and final conclusion is that these forms should be designed somewhat flexible in nature. The proposed forms are specifically described as follows:

**Exhibit No. 1 (Form 1110 Rev.)—Bridge Inspection Report—Covers Masonry, Steel Bridges and Trestles**

This form is designed to be filled out and used by the bridge inspector going over the line for each individual masonry, steel bridge or trestle. The size of the form is 5 in.  $\times$  9½ in. and can be cut without waste from standard stock. This size will also fit a coat pocket. The sheets may be bound into a book with one or more perforated sheets above each fixed sheet or they may be used in a looseleaf field book. The form can be printed so that a duplicate carbon copy (or a triplicate) can be made for the purpose of furnishing copies to those under whose supervision the maintenance of bridges is performed. The remarks column has been left unruled so that defects found can be referred to in detail. In the same or a separate notebook the inspector can carry a form of similar size, described below:

**Exhibit No. 2 (Form 1110-A)—Bridge Inspection Report—Covers Wooden Boxes and Pipe Culverts**

This form is the same size as Exhibit 1 and designed for wooden boxes and pipe culverts. It will permit of listing a large number of these minor items on one page and in a like manner Exhibit No. 1 duplicate (or triplicate) carbon copy can be made for filing with interested parties. Some roads may wish to show inspection of masonry boxes and arches on this form instead of on Exhibit No. 1.

**Exhibit No. 3 (Form No. 1110-B)—Bridge Inspection Report**

Exhibit No. 3, as can be noted, is a summary report which may be compiled from the daily inspection reports. Reports of this kind can be used for any particular period or any series of inspections. It is necessarily a large sized form, 11 in. by 17 in., and the space provided will permit of showing the information for both the inspection forms—namely, Exhibits No. 1 and No. 2.

**Action Recommended**

The Committee recommends Forms 1110 Rev., 1110-A and 1110-B, together with the explanatory text, for inclusion in the Manual.
